No. 1235. Vol. XXXI.—JANUARY 4, 1884.

THE REPRODUCTION OF NEGATIVES BY MEANS OF GELATINE PLATES.

With regard to the production of the duplicate negative, little remains to be said beyond what we have already stated a fortnight ago in connection with the intermediate positive—so far, at least, as the actual manipulations are concerned. If, as we recommend, a positive by superposition be first made, and the second negative is to be enlarged or reduced from the original, some optical means of effecting the purpose will, of course, be necessary; but with this part of the process we have nothing to do in this article. The operations of exposure and development will be the same as those detailed in the previous article, namely, full exposure with a rapid development suddenly checked at a certain point from intensification is proceeded with slowly.

In the matter of "dodging" or improving the original negative there are several ways of proceeding which, as they apply equally to the treatment of the positive and the reproduction, may be described here. Supposing that all has been done that is possible by judicious development, it may still happen that local treatment affords a means of further improving the gradations of either positive or negative. The general treatment during development answers perfectly with a negative that is merely too uniformly dense or the reverse; but in cases where there exists a want of contrast or an excess it will frequently happen that local treatment will be necessary in order to secure the best result, and this may be applied either to the transparency or the negative, or to both.

Take the instance of a negative in which the distance being well lighted is fully over-exposed, and, in consequence of forcing the less exposed foreground, has become too dense to print properly without masking the negative. Now, masking portions of a negative when printing upon albumenised paper is a comparatively easy operation, as the effect can be watched as the operation proceeds, and the means altered or modified from time to time to suit circumstances. But when it comes to the production of a picture by development (be it on carbon tissue or a gelatino-bromide plate) it is absolutely needful that the remedial means be perfect—a result that can only be obtained by pure accident or after repeated experimental trials. Hence the plan of masking becomes a somewhat troublesome, if not hazardous, one in connection with developed work.

But, without any masking, if it be found that the foreground of the transparency made from such a negative as that described above has become too heavy by the time the details in the distance have made their appearance, it is possible, by careful local application of a reducing solution to greatly modify the character of the image. While bearing this in mind, it should always be observed that the finer details—that is, the high lights in the transparency or the shadows in the duplicate negative—must always be looked to in preference to the other portions of the image; for the former cannot be *created* after development is completed, whereas the latter may be easily destroyed, reduced, or modified. For this reason a full exposure is always beneficial.

Of the numerous reducing solutions with which we are acquainted we give the decided preference to those which perform their work in one operation, and which, therefore, enable the effect to be watched as it proceeds. When two operations have to be gone through—one of which converts a portion of the image into chloride or iodide of silver to be subsequently dissolved by the application of a second solution—the final result cannot be accurately judged until after the performance of the second operation, when it will probably be found that the effect is not precisely that sought nor that which might be gained, and either that the image is spoilt or that it is requisite to repeat the double operation with the recurrence of a similar amount of uncertainty. If a slight error of this description occur in the treatment of the positive, it may, most probably, be remedied in the negative; but it is obviously preferable to secure the desired effect in each separate stage.

Of the single operation methods we know nothing better than a very dilute solution of Holmes's ozone bleach, or of *eau de javelle*, or Labarraque's solution. The more dilute the solution the better and safer will it be, though the process will be more prolonged. With a dilute solution the whole surface of the negative may be covered by immersion in a dish, and the plate then being taken in the hand the reducing agent is diligently applied to the portions which require it by means of a brush or tuft of cotton—an occasional departure from the strict boundary or a flooding of the whole surface tending to prevent any sudden line marking the area of treatment.

A mixture of cyanide of potassium and iodine, or even of hypo. and iodine if used very weak, also answers well; while of the double operation methods, chloride of iron or, better still, very dilute *aqua regia*, followed by re-immersion in the hypo., answers well. A convenient solution—which is practically, so far as its action is concerned, a mixture of nitric and hydrochloric acids—is made by dissolving common salt in nitric acid and diluting to the proper strength.

A variation of the double-method plan is to apply the hypo. or cyanide solution first, and, after slightly rinsing the surface to remove the surplus, to apply ferric chloride or oxalate or hydrochloric acid in very dilute solution. This plan is not, however, equal to the others, and is, moreover, especially when hypo. is employed, likely to leave a veil on the clear parts of the picture.

It is better to remove thoroughly all traces of hypo., first of all, by washing, and afterwards treating the film with extremely dilute *eau de javelle*. This latter is superior to alum, as it leaves no veil of sulphur, sulphide of silver, or alumina on the clear portions.

PHOTOMICROGRAPHY.

The image is received upon the focussing-screen, placed, and supported at any convenient distance in a suitable manner. The apparatus is supplied with a special chromatic polarising arrangement, that permits of the reproduction of objects, which, on account of their inactive colours, have not hitherto been permitted to enter into the domain of photography. With this special apparatus, the operator can bring the object to a monochrome scale, which can be infinitely varied by simply turning a button. "Negatives remarkable for their brightness and detail can be taken instantaneously upon wet collodion." Upon referring to the *Comptes Rendus de l'Academie* for 1857, page 213, we find in a brief note some remarks from M. Bertsch, which we suppose have particular reference to this instrument:—"Diatoms of guano were magnified 500 diameters; animalculæ to 500 and 800 diameters, and illuminated by oblique light, without diffraction, or interference lines; blood globules to 500 diameters, each taken in the fraction of a second. Crystals of salicine, as seen by parallel polarised light, were imaged—one by the ordinary, and the other by the extraordinary ray. In superposing these, and rotating them on their axes, until coincidence of the two rays, it will be remarked that the complementary tone of a photographic colour exercises no action upon the sensitive substance, and *vice versâ*. The experiment, which can be repeated under different methods, furnishes useful guidance in photography, and to opticians certain data upon the best achromatic medium in the construction of objectives applied to this art." The photomicrographs taken with this apparatus called forth the eulogium of the late Sir D. Brewster. The expense is no doubt largely due to the costliness of the prism, as well as to the great care in the general construction.

M. Bertsch, in his remarks later upon M. Jules Girard's communication to the Photographic Society of France, stated that for many years he had employed homogeneous illumination, by a small chromatic polarising apparatus, which permitted him to give the field a colour adapted to the object, so that each part would be reproduced in the tone that belonged to it, without the field being solarised; and by its means M. Neyt had produced beautiful photographs of vegetable tissues. [See this Journal, July 3, 1868.] Mr. Richards exhibited and described the camera to the Photographic Society of Great Britain in 1863. [See *Journal of the Photographic Society*, 1863, page 273.] Pictures could be made on Talbotype paper, one yard square, in four seconds.

This is the kind of instrument made by M. Hartnack and very successfully used by M. Neyt, from whose paper in the *Bulletin Belge de la Photographie*, and reprinted in this Journal, April, 1862, we extract some additional detail. The prism with its parallactic movements, though of considerably greater cost, was adopted in place of the usual mirror, as it is less influenced by the wind. The condensing lens is two and three-quarter inches in diameter. Three converging lenses, with a separate, or conjoined motion, are placed in its focus; also two diverging lenses, complementary to the focus of the condensing lens, to obtain parallel light when lenses of a large field are used. M. Neyt remarks that the lenses are achromatised for the yellow and violet rays. In ordinary apparatus, it is the yellow and red that are reunited, and in such a case there would be the chance of too much heat on the object, and a visual, instead of a chemical, focus. The instrument ordinarily transmits the rays horizontally. In reproducing *infusoria* this is inconvenient as regards the fluid being in a vertical plane, and the animalculæ constantly seeking the lower edge, and thus continually passing out of the field. To counteract this, so far as we can learn from the description, the plane of the stage is set horizontally, the objects illuminated by a prism of total reflection, and the image thrown horizontally by another prism—which may be of quartz, and as small as possible—set over the objective. This is similar to the plan already described. The loss of light from the two prisms, M. Neyt remarks, amounts to nothing. A series of diaphragms are adjusted immediately beneath the object. He adds to these a compensating prism, either at the point where the rays leave the instrument, if he use it horizontally, or in the dark chamber, if he use it bent. The focussing is made on a focussing-glass of an ordinary camera without a bottom, and then the intensity of the illumination is regulated. When the focus is exactly on the object, the image of the sun is seen at the same time on the ground glass. The focus is then thrown a little behind, until a blue point is obtained in the centre of the field, and the adjustment of the lenses is left at the point where this spreads itself over the entire image, it being the *maximum* amount of chemical illumination. The image is received on the sensitive surface in the usual way, but before it is exposed in the camera the light is intercepted by a yellow-coloured glass, and the room well shaded from light, the exposure being made by the sudden removal, and replacement of the yellow glass according to the time required. With the magnification of 1200 diameters seven or eight seconds sufficed; for 300 diameters the fraction of a second. The exposure was sometimes made by the use of a winged shutter. Preference was given to the wet collodion process. For the representation of *infusoria*, their movements being extremely rapid, this exposure was found to be too long to secure the vibratory action of their *ciliæ*. Poisoning them, distorted and convulsed their form; consequently, the electric spark or a galvanic current was employed. The two poles from a Daniel's battery, or small induction coil, were put in contact with the drop of water. The circuit was interrupted near its source; the movements of the animalculæ were followed through the yellow glass—the contact for the transmission of the current being effected at the desired moment; then the exposure made, whilst the objects remained transfixed in their different attitudes. With yellow- or brown-coloured objects, which do not admit the actinic rays, a small polarising apparatus was used to modify the general tint, and render it more photogenic. M. Neyt advocated the use of such images for the reproduction of copper plates, after the heliographic process of M. Chas. Nègre.

To lessen the risk of vibration in a somewhat similar apparatus, provided with a long mirror with parallactic movements made by M. Dubosq, of Paris, Dr. Maddox had the window closed by two shutters, each sliding in its own frame fixed at the side of the window. The lower one had a square aperture cut out at the right height near the centre, and on each side, an oblong one fitted with a sliding frame, provided with a pane of non-actinic glass and curtains. The square brass plate of the apparatus was fastened upon a stout frame with a foot that could be clamped, so as to keep the frame rigidly vertical, at the end of a long stout, blackened, baseboard, which was iron grooved at the sides, and supported upon four strong double triangle legs. At the opposite end of the board was an open frame, with two horizontal sliding bars, to hold the screen and plate; the frame being hinged to a wide foot made to slide in the side grooves. This frame had slight movements for adjusting the plane of the sensitised plate, if required, to the plane of the objects. In use, the lower window was thrown up, the shutter drawn down, the mirror passed out through the square aperture, and the square frame brought close to the shutter, *but not to touch it*, the foot being clamped in position, whilst light-tight flaps of cloth prevented all leakage of light into the dark room. The object on the stage was illuminated, either by direct sunlight from the mirror, or this by the light reflected from the mirror of a heliostat, placed in proper position outside on the window sill. Fine card, cemented to plate glass, formed the focussing-screen. Sometimes the stage, with its bar, pierced diaphragm, and objective carrier, was removed from the end of the small body tube, and a large microscope centered by guides was placed on the base-board in a horizontal position, the achromatic condenser being correctly set in the optical axis of the large condenser. A large ammonio-sulphate copper cell was hung to the shutter outside before the large lens, or a smaller cell, with a stronger solution, was fixed next to the achromatic condenser.

The facilities of this method, we note, are great, as after work, or in case of rain, or want of sunlight, the square frame with mirror could be unclamped, and drawn inside, the other part of the apparatus remaining *in situ*, the shutter thrown up, the heliostat removed, and the lower window closed. The sliding panes of red glass admitted of examining the sky, and judging of the continuance of sunshine, as well as of admitting ordinary light into the dark room, the whole plan being a luxurious mode of working. For judging of an enlargement, a card could be fastened against the closed door opposite the window. As a caution *do not* look through the empty tubes to judge of the centering when the full blaze of light is directed through them from the large condensing lens, as we know from this inadvertence Dr. Maddox was obliged to desist from all serious work with the microscope for a considerable period. Mr. Wenham worked with a smaller kind of solar microscope fixed to a shutter with a hole cut in it, provided with a sleeve for the facility of operating, non-actinic light being admitted by an aperture towards the top.

DISTORTION CAUSED BY THE SWING-BACK.

We have been asked if an accurate or absolutely non-distorted photograph can be obtained when employing a swing-back to the camera.

To reply to such a query we have to inquire what, in this sense, is meant by distortion? The displacement of the vertical lines in an architectural subject, so as to bring them into parallelism, which is the function of a swing-back as applied to architecture, evidently must not fall within this category, seeing that the swing-back is conducive to the avoidance of distortion. But in a landscape the matter is quite different.

It has been shown in a former article in this Journal that in landscape work the swing is indispensable in order to secure sharpness in the foreground; but by this employment of the swing-back the image is thrown upon an oblique plane, by which, while the definition is improved, an error in orthographic projection is undoubtedly introduced, inasmuch as by the requirements of conjugate foci no two parts of the picture in a vertical direction will be taken with a lens (practically) of the same focus. The foreground will be sensibly enlarged in comparison with the distance.

The nature and extent of this unrecognised class of distortion can be readily perceived by taking a view of any convenient scene with a lens having a stop so small as to define the distance equally well with the foreground when the ground glass is in a strictly vertical position. Next take another view without moving the camera or altering the lens, but employ a larger stop and swing the ground glass until sharpness of the objects in the immediate foreground is secured.

Upon comparing the two photographs thus taken it will be found, on measuring by means of a pair of compasses the distance between any well-marked object in the foreground and of another object in the distance, that these measurements are not alike in both; but that in the picture last taken, in which recourse was had to the functions of the swing-back, the distance between the two points indicated will be greater than that in the former.

LANTERN TRANSPARENCIES BY THE ALBUMEN PROCESS.

Resuming the subject of the production of lantern slides by the albumen method where we left off last week, we shall now proceed to the sensitising of the plates.

The formula for the bath stands thus:—

Nitrate of silver	2 ounces.
Distilled water	1 pint.
Iodide of potassium	5 grains.
Glacial acetic acid (52°)	2½ ounces.

The method of mixing is as follows:—First, the iodide is dissolved in the water, then the nitrate of silver is added, and the whole well stirred with a glass rod until the silver is dissolved. The solution is then filtered, and, finally, the acetic acid is added, when the bath is ready for use. The object of adding the iodide is to saturate the bath with iodide of silver in order to prevent any of that salt being dissolved out of the film after it is once formed, which otherwise might happen. Sufficient of the solution to cover the size of the plate to be sensitised is poured into an ordinary dipping bath. The plates are then immersed (with the precautions usual in the wet collodion process) for a period of half-a-minute to a minute only. In summer, when the solution is warm, thirty seconds will be ample, and in winter the longer time may be allowed; but it should never be exceeded, as the sensitising takes place very rapidly, and a longer time than is necessary is liable to affect the plate injuriously.

By continual use the bath will become discoloured, as does that employed for sensitising albumenised paper. It may, however, be decolorised by simply shaking it up with a little kaolin. If the bath be much used—or if it be allowed to stand in an open vessel when out of use—the addition of a small quantity of acetic acid from time to time will be necessary. Some operators prefer to employ a new solution for each batch of plates. In this case the plates are usually sensitised in a flat dish, when, of course, a much smaller quantity of solution will suffice. When the plates are taken from the bath they are placed in a dish of distilled water to remove the major portion of the free nitrate, after which they are thoroughly washed under the tap to eliminate the remainder. They are then reared up on a pad of blotting-paper to drain, and are afterwards dried.

The drying may be accomplished in any of the boxes used for gelatine plates, and, as the film is very thin, it does not retain much moisture; therefore the plates dry very much quicker than do gelatine. As many who do not possess properly-constructed drying boxes, or cupboards may like to try the albumen process, it may be mentioned that one, suitable for the purpose, may be extemporised by taking an ordinary box, or packing case, and placing it in front of the fire for an hour or so to thoroughly desiccate the wood. In this the plates are placed on some dry blotting-paper, and in a few hours the plates will be perfectly dry, the moisture from them having been absorbed by the desiccated wood. We have ere now used a common hat box when anything more suitable was not at hand. It may be as well to mention here, for the information of those who have never prepared albumen plates, that it must not be expected that the films will be dense and creamy like those of gelatine, or even of wet collodion, as they are always very thin and transparent.

Printing the transparencies may be effected either in the camera or by superposition, the latter being the method usually followed; but if the negatives be a different size to that of the required slide the camera must be used, and with it a lens capable of giving good definition with a large aperture. For compared with wet collodion the albumen process is slow, and in comparison with gelatine *very* slow indeed, although it is not so slow as the gelatine chloride process. With the camera the exposure will necessarily be somewhat long, and, as a rule, when prolonged exposures have to be given, the colour of the image is rarely very satisfactory.

In printing by superposition, either diffused daylight or artificial light—such as a gas flame or a paraffine lamp—may be employed. With regard to the time of exposure little can be said, as all will be dependent upon the source of light employed, the distance the plate is placed from it, as well as upon the density of the negative itself. Therefore, the experimentalist must determine this matter for himself. This he can easily do by exposing a plate or two under a negative of average intensity, giving different times for different portions of it, and then developing. One or two plates exposed in this way will enable a very correct judgment to be formed as to the exposure required in future for every class of negative. When once this is arrived at it remains constant, because, unlike the gelatine, each batch of albumen plates prepared may be relied upon as being of equal sensibility.

We now come to the development of the image. This at one period was treated, and preserved, as a great secret. The developing solution after all is very similar to that used in the wet-collodion process before the iron developer was introduced, except that it contains a little citric acid, and that *it is employed warm*. A good developer is as follows:—

Pyrogallic acid	25 grains.
Glacial acetic acid	½ ounce.
Citric acid	10 grains.
Water	10 ounces.

This solution had better be made and kept in a Florence flask, so that it can be heated and kept warm over a spirit lamp when required for use.

The exposed plate is first placed in a dish of distilled water, heated to about 150° F., until it has acquired that temperature. It is then removed, slightly drained, and flooded with the developing solution, which has previously been heated to about 130° or 140° F. Immediately before the solution is applied it must have about four drops, per ounce, of a five-grain solution of nitrate of silver added. If properly exposed the image will quickly appear, and by the way it comes out it may be judged if the exposure has been rightly timed or not, similarly as in the development of plates by any other process. As the films are so very thin and transparent the density of the image can easily be judged of by transmitted light. It is always best to err on the side of under- than over-density, because, in the latter case, the slides will always appear dense and heavy on the screen; whereas if they be slightly thin it may, to some extent, be remedied in the toning. As a guide in the development, it may be borne in mind that the more fully the plates are exposed and the more rapidly they are developed, as also the less silver employed in the developer, the warmer will be the colour of the image; while the slower the development, either from the solution being cold or the plate under-exposed, or if too much silver be used, the more the picture will approach an olive-brown tone.

As the development proceeds the plate must be carefully watched for stains or fog. If any appear the plate must at once be washed under the tap, and the surface rubbed with a pledget of cotton wool, which will remove them. The development can then be recommenced with a fresh batch of solution and silver, repeating the treatment with the cotton wool if found necessary. When the development is complete, the plate must be thoroughly washed under the tap to remove all traces of the pyrogallic acid, which, if allowed to remain, would tend to injure the toning bath.

The plate is now ready for fixing and toning. This is usually done in one bath, which is made as follows:—Half-a-pound of hyposulphite of soda is dissolved in half-a-pint of water; then three grains of chloride of gold, dissolved in two ounces of water, is added very gradually, and with vigorous stirring. After standing twelve hours and being filtered it is ready for use. It is then placed in a flat dish and the plate immersed. The iodide is quickly dissolved out, but the toning proceeds slowly—from a quarter- to half-an-hour or more being frequently required to obtain deep, rich tones. But much depends upon the colour and density of the image at starting. When the desired tone is obtained the plate is well washed under the tap and afterwards soaked in plenty of water, and again rinsed to ensure the entire removal of all traces of the hypo. Indeed, as much care should be bestowed on this part of the operation as in the case of gelatine negatives, in order to ensure permanency.

Alkaline gold toning (after fixing in plain hyposulphite and thoroughly washing) may be employed instead of the double fixing and toning bath; but the colour obtained in our hands and to our taste has not been so satisfactory as by the method just described. which is that used by MM. Ferrier and Soulier.

ATMOSPHERIC MOISTURE.

Considering the important part played in photography by the moisture-carrying power of the atmosphere, there is good cause for surprise at the paucity of exact observations in connection with it, and at the rarity of instances to be met with where scientific treatment is bestowed upon the measurement of the amount of water present in the air. Where, outside scientific works, for instance, are data readily available to show the amount of water a room of given size will carry? And at how many studios will an instrument be found for indicating the amount present—an hygrometer, in fact? Yet it cannot be denied that for drying dry plates, gelatine tissue, and, in a lesser degree, albumenised paper, such knowledge and such instrumental assistance is of high value. At the present season, however, the water vapour in the atmosphere often renders its presence manifest in another peculiarly unpleasant manner, and in a way that bodes no good to apparatus, negatives, or pictures. We refer not to fog, but rather to what might be not inaptly termed "dew."

In most parts of the country the day before Christmas Day just past presented in the highest possible degree those phenomena of universal humidity that can only be seen to perfection in these isles. The day was by no means cold; there was no fog, neither had rain fallen; yet the flags of the footpath were damp (almost wet), the walls covered with moisture, the trees dripping as though a smart shower had fallen, and everything out of doors was dank and miserable. Indoors the state of affairs was less marked, but sufficiently unpleasant. In apartments where no fire had lately given off its cheering rays something very like the outside conditions prevailed in miniature. Negatives lying about were to be seen covered with a thin film as though they had been breathed upon, and newly-mounted pictures looked limp though the paste had been allowed hours wherein to dry. Apparatus was equally damp, and the brasswork of lenses was likewise covered with the all-pervading moisture.

The explanation is easily given. The previous day had been decidedly cool, and on the day in question the wind had brought a warmer air containing as much moisture as it could possibly hold at the temperature. The consequence was that, wherever an object with not too porous or rough a surface and of lower temperature came into contact with the new air, as it might be termed, the temperature of the latter was lowered, and, in consequence, the water it contained as vapour became precipitated, naturally, upon the very object that caused that precipitation, the closely adjacent layers of air being the first to become cooled and give up moisture.

The danger of this precipitation of thin films of moisture upon negatives need not be dilated upon; and if by any chance negatives so affected are stored without removing the moisture, or if it be deposited upon them when they are kept in closed boxes that are only occasionally opened, the result will be the almost inevitable cockling up in ridges, or honeycombing, of the whole film so familiar to some photographers. Gelatine negatives not varnished will be in danger of causing the albumenised paper to adhere so firmly as to be irremovable without damage, or it may result in "setting off" of the silver from the paper, only to show its effects as a bad stain after the lapse of time.

A remedy—or, at least, a partial one—is not difficult to find. It simply consists in keeping the apartment warm where negatives or apparatus are stored, or, where that is difficult, to keep doors and windows well closed so as to keep out the moist air till the cold objects of the room may, perchance, become more assimilated in temperature to the outer air; for it will be understood that this precipitation only occurs when objects are brought into contact with a warmer atmosphere containing much moisture. It is no special property of "damp air" to give off its moisture in this fashion; it only does so to cooler objects. This fact carefully borne in mind may save much anxiety and trouble.

Apparatus of wood should always be put aside in the driest and warmest corner possible, if any store be set by it, as it is far easier to injure or put out of working order a camera or dark slide, &c., by damp, than it is to cure it by removing damp that has gained access to them.

Another very fertile cause of evil is the putting away of newly-mounted cards and cabinets without their thorough desiccation, as, when this does happen, it is almost sure to lead to fading prints. A picture freshly mounted upon its card will be drier after the lapse of an hour with an average state of the atmosphere than at the close of a whole day under such atmospheric conditions as those of which we speak. The great secret, therefore, for avoiding the evils that follow in the train of damp may be said to be the use of heat beforehand; and if principals would give attention to this point they would find it really economical, for not only would better work be done—better through the absence of moisture about printing-frames and pads and all printing-room *paraphernalia*—but the *employés* would work to better advantage, as well as with greater comfort, which is a point that was well put at a meeting of the Society of Photographic Operators in New York the other day.

In the drying of carbon tissue the hygrometric state of the air is a very important factor, for with a comparatively thick film of gelatine holding a large amount of water it cannot be expected that it will dry without special precautions being taken when the atmosphere is already loaded with moisture. The inconvenience of tissue dried too slowly is well known. In its way it is as troublesome as when over-quickly desiccated.

Similarly, with albumenised paper, artificial heat is practically a necessity if negatives are to be kept uninjured; for though a certain amount of moisture, as long since pointed out, is a necessity for the production of the best tones, the carrying to extremes the amount present will be equally productive of evil.

We cannot too strongly lay stress upon the need for decreasing the relative amount of water present in the atmosphere of a room by the simple expedient of raising its temperature in the department where mounting is carried on. If there be one condition of things more than another which can be shown to conduce to fading of prints it is the presence of moisture. Whenever the atmosphere is in such a state that it can carry little if any more moisture—and this may occur in other than the winter months—there is danger, unless artificial heat be applied, of mounted pictures being stacked away damp, and, as they are usually sent out in dozens or so, remaining in the receiver's hands for weeks or longer, it is next to impossible for the individual *cartes* or cabinets to become quite dry unless separately exposed. We are convinced that a very large number of instances of faded prints may be traced to their having been mounted upon a damp day when the whole of the moisture from the mountant has not been expelled, and the pictures have been sent away practically damp.

It will thus be seen that the presence of a moisture-laden atmosphere is productive of as much danger as inconvenience, and the best preventive against evil is a constant elevation of temperature of all apartments where photographic work is carried on or materials and negatives are stored.

THE frontispiece of a recent number of *The Illustrated London News* consists of an admirable engraving from a photograph by Mr. John Thomson, F.R.G.S., better known among his friends as "China Thomson."

SUCH was the rush of business at the Patent Office on the first day of the new year—on which day the new law relating to patents came into force—that no fewer than two hundred and sixty-six new applications for patents were received. On referring to our list of patents, given in another page, it will be seen that of these photography furnished a fair share.

WITH the close of the old year two new French photographic journals have made their appearance, namely, the *Bulletin Officiel de la Société des Employés en Photographie* and *Le Progrès Photographique*, both of which appear monthly. M. Leon Wulff, the editor of the latter-named journal, announces in his introductory preface in the first number that *Le Progrès Photographique* is but a continuation under another name of *La Revue Photographique*, which ceased to appear in 1865, and of which he was for about twelve years the editor. Subsequent to that date, however, another *Revue Photographique* was started as the official organ of the *Société Francaise des Archives. Photographiques, Historiques et Monumentales*, and which is now in its sixth year.

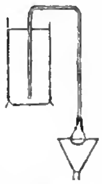
IN this country, too, a high-class scientific journal, under the title of *The Science Monthly*, has reached its third number during the present month. It is published by Mr. David Bogue, of St. Martin's-place, and its general get-up is of a character rarely met with in English journalism. In addition to original articles by eminent writers on different branches of general science, it contains a monthly review of progress and novelty classed under special departments, Photography, together with Experimental Physics, Electricity, and Chemistry, being treated under the head of *The Laboratory*. The columns headed respectively *The Library*, *Topics of the Time*, *Table Talk*, *Summary of News*, *The Observatory*, *The Museum*, *The Workshop*, &c., &c., sufficiently speak for themselves. A series of articles, entitled *Leaders of Science*, is admirably illustrated by phototypic engravings by Meisenbach's process. Those which have already appeared are portraits of Sir Geo. Biddle Airey (late Astronomer-Royal), Sir John Lubbock, and Sir William Thomson.

WE are pleased at receiving from an enthusiastic and clever American amateur, Mr. George H. Johnson, of Bridgeport, Conn., a genial letter with which he encloses several excellent examples of his photographic work. One of these is a characteristic full-length portrait of his friend and neighbour, the world-renowned P. T. Barnum, for whom he is about to photograph the nearly equally-renowned "Jumbo" in several attitudes. In the Barnum winter quarters in Bridgeport there are forty elephants. What a chance for Mr. Johnson! Excellent use is made by that gentleman, in his private business, of the capabilities of photo-mechanical printing.

ON the subject of transparencies Mr. Johnson says:—"I have been trying some of Mr. Wm. Brooks's collodion emulsion for this purpose but incline to give the preference to some made by a formula of Mr. H. J. Newton's. I devote quite a considerable portion of my spare evenings to transparencies, and have probably made more of them than any amateur in America." We are not unacquainted with Mr. Johnson's ability in this direction, having heard a mutual friend, who possesses examples of his work, speak of them in high terms.

A VERY ingenious and simple method of filtering large quantities of fluid, without the necessity for the constant attention involved in the repeated filling up of the funnel, has been devised by Mr. E. E. Robinson, who sends an account of it to our contemporary, the *Chemical News*. Appended is an illustration of his method described in his own words:—

"When large quantities of liquids, such as reagents, have to be filtered in the laboratory, it is often convenient to have some means by which the filter is kept filled. The usual 'bird-fountain' method which is applicable in some cases, has the disadvantage of requiring the inverting of large bottles or flasks filled with liquid, and besides this it does not maintain the liquid at a constant level in the filter. The following apparatus has been found more convenient.



To the longer limb of a syphon is attached a short piece of india-rubber tube projecting a little beyond the tube; the india-rubber is closed by the narrow conical stem of a small glass globe which floats on the surface of the liquid in the funnel. When the liquid rises to a certain height the float is lifted, and stops the flow of the liquid, the narrow stem on the float which passes some distance into the syphon acting as a guide. The apparatus keeps the liquid in the funnel at a constant level, and may be left without attention until the filtration is complete."

THE first meeting of the Photographic Club, in their comfortable new quarters at Anderton's Hotel, was attended by about thirty members and visitors.

WHAT is an "*optical* lens?" We inquire because we frequently see this phrase employed in the advertisement of an "optical lens" manufacturer in the great republic. Month after month this apparently tautological term stares us in the face when glancing over the advertising pages of a New York contemporary, and we find ourselves asking if there are any lenses which are not optical.

THE dangerous properties of celluloid are again troubling the non-technical world, if we may believe a paragraph which appeared in the *Globe* a few evenings since. The writer is evidently not aware of the name of the material of which he speaks so seriously, and certainly is not acquainted with its composition, or his remarks would have been more forcible. It appears that as a couple of persons were playing billiards in a *café* in the Boulevard Poissonnière, Paris, a rather sharp "cannon" caused the balls (which were of "sham ivory") to ignite, with, fortunately, no more dangerous results than to destroy themselves and set fire to the cloth of the table—to the amusement of the onlookers and the indignation of the proprietor. The latter talks of bringing an action against the individual who supplied the balls; meanwhile their fragments are to be analysed.

AN announcement of interest to photographers is made, namely, that the duration of sunshine recorded at Greenwich Observatory last week was—*nil*.

WE have worked celluloid in almost every conceivable way. We have scraped, filed, drilled, sawn, and hammered it. The photographic form known as "celloidin," which is simply solidified collodion, is, when perfectly dry, so hard that it requires a heavy hammer or a hatchet to break it. We have performed even this last operation without any sign of ignition or explosion. As a matter of fact, no form of celluloid or celloidin we have ever met with, though in comparatively small masses, will ignite readily, even in a gas flame, unless held there for some time, and when removed immediately "fizzles" out. We, therefore, take the billiard-ball story with the customary grain of salt.

The improved carrier for lantern slides which Mr. McKean brought under the notice of the Edinburgh Photographic Society at their last meeting is likely to prove very useful. It provides the means of effecting the changing of the slides in the lantern with a degree of rapidity so great that the eye can scarcely appreciate the act. We have had one of them made, but modified in such a manner as to allow the picture to slide horizontally, the propelling force being a spring instead of gravity. This answers in cases where, owing to the construction of the lantern, the vertical movement could not be adopted.

The whole theory of light—not to speak of heat and electricity—is built upon the existence of a hypothetical ether pervading all space, which must of necessity be possessed of properties of elasticity, &c., almost beyond belief when the properties of the most rarified of terrestrial substances are compared with it. "Rays" of light are transmitted by it in waves in a manner something like, yet different from, that in which sound waves pass through air, and although the properties of the ether are such as can only be studied by mathematicians of skill, it is, nevertheless, useful to form some mental conception of the mysterious entity so closely wrapped up with the operations of our art. With the view of aiding the forming of such a mental image, we borrow the following abstract from a collection of the works of Professor Stokes:—

"Suppose a small quantity of glue dissolved in a little water so as to form a stiff jelly. This jelly forms, in fact, an elastic solid; it may be constrained, and it will resist constraint and return to its original form when the constraining force is removed, by virtue of its elasticity; but if we constrain it too far it will break. Suppose, now, the quantity of water in which the glue is dissolved to be doubled, trebled, and so on, till at last we have a pint or a quart of glue water. The jelly will thus become thinner and thinner, and the amount of constraining force which it can bear without being dislocated will become less and less. At last it will become so far fluid as to mend itself again as soon as it is dislocated. Yet there seems hardly sufficient reason for supposing that, at a certain stage of the dilution, the tangential force whereby it resists constraint ceases all of a sudden. In order that the medium should not be dislocated, and therefore should have to be treated as an elastic solid, it is only necessary that the amount of constraint should be very small. The medium would, however, be what we should call a fluid, as regards the motion of solid bodies through it. The velocity of propagation of normal vibrations in our medium would be nearly the same as that of sound in water; the velocity of propagation of transversal vibrations, depending as it does on the tangential elasticity, would become very small. Conceive now a medium having similar properties, but incomparably rarer than air, and we have a medium such as we may conceive the ether to be, a fluid as regards the motion of the earth and planets through it, an elastic solid as regards the small vibrations which constitute light."

A writer in *La Nature* adds another to the list of experiences with toughened glass. He narrates that for two years past he had been in the habit of using a capsule made of this material for heating liquids, and even evaporating to dryness, and often he had tested it by throwing it from a height on to the floor. Some days since, after cleaning it, he left it upon his work-table and went out of the room, but had scarcely closed the door when he heard a loud noise. On quickly returning he found his evaporating dish no longer visible, except in the shape of a number of splinters scattered about in all directions. This is but another example of a fact well known as to toughened glass; it will stand hard knocks, but, at the same time, is liable any moment to fall to pieces without any concussion whatever.

In the *Electrotechnische Zeitschrift* a description is given of a battery which acts only in the light, and which, when a galvanometer is placed in circuit, appears to act upon it directly in accordance with the strength of the light; in fact, the intensity of the incident light is said to be capable of exact measurement by its aid. If the facts should prove to warrant the assertion (which we are much inclined to doubt) a most useful photographic instrument will have been devised, and some remarkable problems solved; in fact, photographic telegraphy would be in the near distance. The battery is made by placing a porous cell containing mercury in a glass jar holding a solution of common salt and sulphate of copper. In the saline solution an electrode of sulphide of silver is placed, and in the mercury one of platinum. When the battery is placed in the dark the galvanometer shows no indication of electric action whatever; but a ray of light falling on the silver plate at once causes the galvanometer to move. From these concise instructions it is within anyone's ability to construct the battery; and, if what we quote regarding its power should prove to be correct, it is impossible to foresee the ramifications to which the use of the instrument would extend.

At the Berlin Physical Society Professor Rowlands' gratings have formed an interesting topic. They had before them at a recent sitting a grating received from Professor Rowlands and a negative taken by him, as also a photograph of the normal spectrum. So searching was the definition of the negative that with the naked eye Dr. Kayser was able to count over seventy-five lines between the two H lines, and with a microscope it was expected that still more would be discernible, as they appeared to form groups.

We have often pointed out how the usual order of exchangeability of chlorine, bromine, and iodine is apt to be reversed by the conditions governing the mixture in which they are formed, and some interesting experiments, recently described by Paul Julius, will show in a remarkable manner how previous conceptions have at times to be modified. Passing a thoroughly-dried current of air into bromine contained in a small Hoffman flask, and so saturating it with bromine vapour, he conveyed it through a tube of very infusible glass, bent at its end into a right angle, the termination being contracted and dipping into a beaker of soda or potassa. When silver iodide was placed in the tube and strong heat applied, it was all converted into bromide. When chloride of silver, previously dried in the air bath at 120° C., was placed in the tube, the stream of dry bromine converted it also into bromide after the lapse of an hour or two. Further experiments showed that chlorine and bromine can be expelled from their silver compounds by the vapour of iodine, though in the case of the chloride from six to ten hours was required to entirely complete the substitution. The whole experiments, therefore, show that any halogen, if used in excess, is capable of expelling any other halogen from its combination with silver.

PREPARING GELATINE PLATES FOR HOT CLIMATES.

Intending to go to India as soon as the season is a little farther advanced, and being desirous of employing gelatine plates, I have for some time been rather anxious regarding the effect upon such plates of the warm water which alone is said to be met with there, especially during the more sultry weather.

Knowing that a greater degree of heat is usually encountered by photographers in the United States of America than those in England, I obtained from the former country a parcel of plates of a good average class, and proceeded to test them by warming my developing solution, fixing bath, and washing water to the temperature said to prevail in Calcutta during the sultry season. To make the trial as instructive as possible I invariably tried an English plate along with the other. The former stood the warm fluid applications quite well; the latter did not. I cannot say that I found any appreciable difference in their sensitiveness.

Finding that the English plate was unaffected by the warm water, I carried the experiment still further and poured over it water whose temperature was at almost boiling point, and still the film remained undisturbed. I had previously observed that the American plate was easy to fix in comparison with the home brand, and I reasoned that some such substance as chrome alum must have been added to the gelatine in the latter in order to harden it, or perhaps prevent frilling, the same substance also conferring upon it insolubility in hot water.

To ascertain if my hypothesis were correct I made ten ounces of emulsion with a gelatine that is rather noted for its softness and easy solubility. From this I separated three ounces, to which I added four drops of a solution of chrome alum, shaking well up. Having coated six plates with the alumed and six with the unaltered emulsion, I marked them, and tried the result. Greatly to my gratification I found that, while the quality of the negatives was excellent on the alumed plates, the film had become so thoroughly tanned as to be altogether unaffected by the warmed developer and washing water; while the negatives obtained on the plain emulsion, subsequently treated in a manner similar to the other throughout, dissolved entirely away.

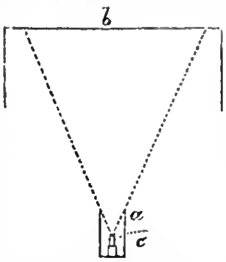
It seems, therefore, that while there are some commercial plates sold in the usual way which will fulfil all the requirements of a tropical climate, it will not be a difficult matter for photographers to prepare for themselves, or get their plate manufacturers to do so, plates which will remain quite unaffected while undergoing treatment with the heated water of equatorial regions.

HERBERT J. RIGBY.

DARK-ROOM LIGHT.—CARRIER FOR LANTERN SLIDES.

DARK-ROOM LIGHT.

DARK-ROOM lighting is an important subject. I shall describe my method of dark-room illumination now that the question of lighting by reflection from coloured surfaces has been brought to the front by Mr. Herbert S. Starnes. *a* is a circular lamp open at the top, and of such a height and diameter as only to allow of the ceiling, *b*, or a part thereof, being illuminated by light direct from the gas or candle, *c*. In my room a part only of the ceiling is so exposed, and that part is covered with a dark orange matt surface, which reflects a soft and pleasant light into every corner of my room. I can see every bottle, and very small articles are quite visible. Moreover, I find the light quite safe, although from habit I expose the plates as short a time as possible to its influence.



This arrangement involves exactly the same principles as that of Mr. Starnes' new lamp. I hope that Mr. Starnes will not think I write in order to take from the merits of his lamp or experiments, or to claim priority in the slightest degree, although I have been working with this arrangement since towards the end of last summer.

I did not think the matter was worth writing to the Journal about, as it is well known that a rapid and neat operator may develope a plate quite satisfactorily by reflected light from a naked peep of gas, shading his plate previous to and during the first stages of development. However, as the matter is to the front, I think it ought to be thoroughly "gone into" and scientifically examined. I must confess to having been a little staggered by some of the results of Mr. Starnes' experiments, but of that more anon.

I may be in error, but I imagine that ordinary light received on a coloured and *very extended* matt surface will give a more pleasant room than any other device. The use of the roof as a reflecting extended surface is a very simple expedient. I am careful to say that I hold this opinion as to extended surfaces lightly, because I have not experimented on the subject so deeply as I would have liked. I have a presentiment, however, that a room will never be properly illuminated from *small* reflecting surfaces without introducing a dangerous percentage of white light. If the light be cut down by double or triple reflection from matt surfaces, then a sufficient *quantity* is not obtained.

While on this question of reflection from matt surfaces, it is well to take cognisance of the fact that a very great deal depends on the nature of the surface employed. Two surfaces may be made with the same colouring material, and even the same proportion per given area, which will give very different results in the spectroscope and on gelatine plates. I explain on this basis to my own satisfaction the apparently anomalous results arrived at by Mr. Starnes.

In carrying out a series of experiments such as the readers of the Journal have been favoured with, very great care ought to be taken that the degree of roughness or pitting on the surface should be the same in all the surfaces experimented on, otherwise the results may be of inferior value. Most of us will remember the class-room experiment with metallic copper surfaces. By reflection or reflections from a comparatively smooth yet pitted surface of copper the colour may be made to vary from the light ordinary "copper" colour through all shades up to a colour not far removed from the colour of blood. Mr. Starnes' suggestion to use cloth material instead of paint shows that he is alive to the effect of difference of surface. May I ask if he has estimated the effect of differences in the various surfaces employed by him?

There is another point hinging on the foregoing, and one that in a colour investigation of this kind absolutely demands attention—that is, the real or absolute photometric value of the light reflected from the surfaces. Mr. Starnes says:—"On the threshold of my experiments in this [production of new reflecting lamp] direction I found how misleading the results of photographing the spectrum—or, rather, the density given on a sensitive film by the spectrum—is when applied to practical photography," &c.; and he proceeds to say that light from an orange surface gave nearly as dense a deposit on a gelatine plate as light from a blue one. As an outcome of his experiments he says "they tend to show that the action of light on a sensitive film is a heat force or, rather, an expansive force."

Now, unless Mr. Starnes has determined the photometric values of the reflected beams from those orange and blue surfaces he has happened to work with, and compared them with the photometric values of the nearest approaching orange and blue colours of the spectrum, I think he has been rather premature in coming to the conclusions he has set forth.

Will he pardon my apparent forwardness in saying a little as to the course he ought to pursue in this investigation? I trust he will, and put all down to the interest I take in the subject and to no lower motive. First, I would have him make two surfaces—one blue and the other orange—and let these surfaces be nearly alike as to roughness, porosity, &c. Next, let him determine their photometric values by the shadow or oiled-paper method, and expose a plate first to the light reflected from the one surface and then to the light from the other, taking care that his plate is at that point at which their values are *equal;* or, if he wish it, from that point at which their values are *equal to the photometric values of the respective colours of the natural spectrum.*

I shall be very much astonished if he arrive at the conclusions he has already announced. Should Mr. Starnes not have the time or not care about doing this and wish me to carry it out, I shall be very happy to do so. He has the apparatus ready, however, and will easily accomplish it in an hour or two at most.

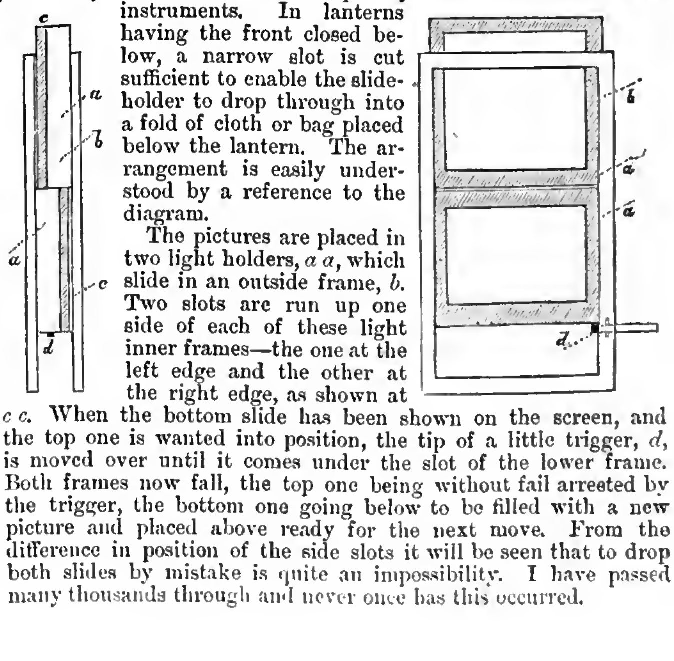
In this way only, or some other involving the same principles, will he be able to give a *practically*, not to speak of a *scientifically*, accurate estimate of the value of various reflecting surfaces for dark-room illumination.

CARRIER FOR LANTERN SLIDES.

I give below a diagram of a simple and exceedingly-efficient carrier for the instantaneous substitution of one slide for another in the optical lantern. I observe the subject has been before the Edinburgh Photographic Society, and a very ingenious device exhibited there by Mr. J. McKean. Perhaps the description of another device which I thought out some years ago may cause some of your readers who contemplate the purchase of a biunial to "tak' a thocht" and keep to a single, provided with a device similar to Mr. McKean's or that I am about to describe.

The carrier now in my possession was exhibited at a popular meeting of the Dundee and East of Scotland Photographic Association two years ago. I think it is simpler in construction than Mr. McKean's, but this is a matter of opinion. It is quite impossible to put anything coenected with it out of order, it having practically no machinery.

Mr. McKean's device requires a modification (although not a very serious one) of the front of the lantern. With this device no modification is required in lanterns where the front plate is supported by four studs, as is frequently the case in first-class instruments. In lanterns having the front closed below, a narrow slot is cut sufficient to enable the slide-holder to drop through into a fold of cloth or bag placed below the lantern. The arrangement is easily understood by a reference to the diagram.



The pictures are placed in two light holders, *a a*, which slide in an outside frame, *b*. Two slots are run up one side of each of these light inner frames—the one at the left edge and the other at the right edge, as shown at *c c*. When the bottom slide has been shown on the screen, and the top one is wanted into position, the tip of a little trigger, *d*, is moved over until it comes under the slot of the lower frame. Both frames now fall, the top one being without fail arrested by the trigger, the bottom one going below to be filled with a new picture and placed above ready for the next move. From the difference in position of the side slots it will be seen that to drop both slides by mistake is quite an impossibility. I have passed many thousands through and never once has this occurred.

As an improvement I intend to have the next one made with all the running parts covered with velvet or other soft material, in order to make all as silent in working as possible. I shall be very happy to forward my carrier to Mr. McKean for his inspection should he think fit. G. D. MACDOUGALD.

DEVELOPMENT AND DIRECT PRINTING OF GELATINO-CHLORIDE PLATES.

As the above kind of plates are likely to become more useful to the photographer for the class of work to which they are best adapted—such as transparencies for lantern slides, window decoration, and enlarged negatives—the question arises which of the two methods will meet the requirements of the photographer best, namely, to have plates that will print the image right out without resorting to development, or plates that with a slight exposure in the printing-frame are afterwards developed.

Having had some experience with both methods, I find the plates adapted for development will do the best service when a number of slides are wanted in the shortest space of time from one negative; beyond that I cannot say anything more by way of preference.

As a rule, photographers will find direct printing far more easy and certain—that is to say, printing out by exposure to light in the printing-frame—let alone the economy of that method, as the citro-iron developer, which is the best on account of the variable tones yielded, is as expensive as the general forms in use. I find, from recent experiments, that plates for direct printing can be made to yield tones almost as variable as those produced by development, by compounding the chloride emulsion with different salts. The samples sent are not toned, but by toning them they can be altered in colour. To place one of these plates in the printing-frame and examine its progress along with the roll of paper is but a brief trespass as regards time, and when printed is taken out, placed in the fixing-bath, and washed. The whole operation demands the least attention of any process extant for producing the same kind of photographs.

A word as to judging the depth to print. With glass you cannot pull it back from the negative and look upon its surface to examine the progress, unless great care be taken in registering its position by using a suitable printing-frame. This is, however, quite unnecessary in the present case, as by looking at the back of the plate on opening half of the printing-frame you will see the progress made easily, the plates are so transparent. When the high lights are well browned that is the stage to stop printing, provided the picture be for a lantern slide. When a gelatino-chloride plate is fixed and examined in the wet state it looks rather thin and weak, but when dry becomes much more vigorous.

For transparencies to be used for enlarging purposes a much finer film can be had on one of these chloride plates than on a bromide one, as the two enclosed examples will show. Both are from the same negative, but are made from chloride and bromide plates respectively, the negative being taken from a paper print. But there is as much difference between the two transparencies in fineness as there is between a negative from a copy and one taken from the original sitter. L. DIXON.

[As the specimens which accompanied this communication are not toned we can scarcely form an idea as to the possible variety obtainable. At present they are all very similar.—EDS.]

TRANSATLANTIC JOTTINGS.

WHICH of our readers will not sympathise with Mr. L. Coe, photographer? who, according to the New York *Times*—

"Is just at present anxious to know who is to pay him for his broken camera. On the 5th instant it occurred to certain policemen that the photograph of Mr. Thomas Davis—a man said to be a professional criminal—would be a desirable addition to the Rogues' Gallery. Thereupon they arrested Mr. Davis, escorted him to Mr. Coe's photographic studio, and directed the photographer to take the man's likeness. Mr. Davis, curiously enough, did not wish to have his photograph taken—fearing, perhaps, that the *Sun* would get hold of it and publish it as a portrait of Holman—so he seized his chair and, using it as a club, irretrievably smashed the camera. For this offence he was again arrested and committed to jail on a charge of disorderly conduct. Of course, he will not pay for the camera, and as the police officers did not smash it they will not pay for it; so that Mr. Coe is naturally in a discontented and gloomy frame of mind."

Our American cousins do not, as a rule, need to copy English mechanical "dodges," as there always seems to be out there a supply sufficient for all demands of ready-made ideas in that direction. According to the *Scientific American*, however, a patent has been granted for a revolving album, of exactly the same construction as the well-known pattern that created so much interest in this country on its introduction many years ago. Our readers have more than once seen the same thing at the exhibitions of the Photographic Society of Great Britain. It consists of a box suspended between two pillars and containing pictures temporarily held in wooden frames which, as the box revolves, slide over one another and continually expose fresh pictures each time the opposite face of the box is brought into view.

According to *Anthony's Bulletin*—the month's engraving for which journal is a portrait of Mr. W. Kurtz—"retouching the negative was one of his suggestions, and he was the first to practise it." There is surely some error here. Mr. Kurtz may have learnt the secret, when it was a secret, on the continent and largely practised by German artists, when English photographers, with one or two notable exceptions, were talking of the superiority of continental skies; but it was in use there long before Mr. Kurtz had a studio. Let that be as it may, the fact remains that Mr. Kurtz is one of the foremost men of the day in his own or any country, and his photographs possess rare excellence and beauty.

The American journals to hand contain accounts of two new developers, one of them being merely an old friend with a new face, and the other an undoubted novelty. No. 1 is Mr. Joshua Smith's "missing link" developer, described before the members of the Photographic Association of Chicago. The formula introduced after a few experiments is simply as follows:—

Lime water	6 ounces,
Bromide of ammonium	12 grains,
Pyro	A small mustard spoonful,

and, as our readers will perceive, the only new point in it is the obtaining of the ammonia from the bromide salt, the mixture producing ammonia and bromide of calcium. Possibly the latter salt may have a slight effect on the colour of the negative. No. 2 has real novelty about it. We make no criticism upon it in this place, but merely content ourselves with placing the formula in this column. We have often brought before our readers the well-known name of Mr. H. J. Newton, to whom the carbonate of soda method of developing is due, and this new process also is the result of his experiments. In brief: it may be said to consist of adding to the ordinary carbonate of soda developer a few drops of iodo-chloride of mercury. Mr. Newton claims for it that a picture may be taken by its aid in one-fifth of the time required by the ordinary developer. If he should be right he will have made the most important improvement in gelatino-bromide plates since Mr. Bennett's discoveries. The proportions are as follow:—

SOLUTION 1.

Bichloride of mercury	30 grains.
Water	4 ounces.

SOLUTION 2.

Iodide of potassium	90 grains.
Water	½ ounce.

Pour Solution 2 into Solution 1, and stir; the red precipitate first produced quickly dissolves. Mr. Newton's carbonate of soda developer is used, and when the image begins to appear a few drops of the above solution are added to it; and "it is surprising to see how this starts the picture," Mr. Newton says. With the full details we give there is no doubt many will experiment with this new developer.

Anthony's Bulletin extracts a considerable portion of our leading article on *The Various Styles and the Mode of Preserving Photographs*, which appeared in our pages of September 21st, and in which we indicated a great want at present existing for some simple, cheap, neat, and expeditious mode of securing photographs singly, so as to exhibit them to advantage and, at the same time, preserve them. With regard to our suggestion the *Bulletin* says:—

"There is no doubt that this want is a positive one, existing in this country as well as in Europe, and we desire to call the attention of persons who cater for the needs of photographers to the subject, and hope that ere long something may be provided as suggested."

According to the *Photographic Times*, Mr. Rockwood—who has been carrying on a series of delicate experiments in photographing the vibrations of a telephone plate—has been following the lead of our own recent experimentalists, and photographing the vocal chords of the human throat with results that were considered, on the whole, so far satisfactory that "further experiments will soon be tried with trained singers, arrangements having been made with Mesdames Patti, Nilsson, Gerster, Sembrich, and other stars of the vocal firma-ment, when Mr. Rockwood's already long list of publications will be enriched by the 'vocal chords' of the above celebrated artists."

A well-known dry-plate manufacturer, Mr. Beebe, paid English-made glass a high compliment at a meeting of the Chicago Amateur's Club, which throws a side-light upon the question of cost of plate-making. He said he would tell them a secret. He had some considerable amount of trouble with defective glass, and finally had settled down to use an English make entirely; for, although it was much dearer than any other kind, it was infinitely better. According to Mr. Beebe, plates really are dearer in proportion in America than in London; and, with the price of materials running up in this manner, no one can wonder that American plates, costing so much in the first instance, should be retailed at a higher price. The wonder would be if they were not still dearer.

SOME ATTEMPTS AT DETERMINING THE ACTINIC LIGHT IN THE STARS BY PHOTOGRAPHY.

When the great comet of the year 1882 was visible, Dr. Gill, Her Majesty's Astronomer at the Cape of Good Hope, attempted to photograph it by means of an ordinary camera attached to the equatorial. Copies of these photographs were in due course forwarded to England. The multitude of stars shown is very striking. The photograph appears mottled all over, and this mottling is due to the light from the fainter stars.

In the summer of the present year Professor Pickering, of Harvard, U.S., showed some negatives of stars taken in the same way, and made remarks upon them before the Royal Astronomical Society. One of these negatives I was allowed, by the kindness of Professor Pickering, to examine while he was in Liverpool, in September. The work that Professor Pickering has undertaken is (1) a photographic map of the whole heavens; (2) a determination of the colours of the stars.

Now, as the action upon the photographic plate increases with the distance from the red end of the spectrum, those stars whose colour inclines to red will come out comparatively faint on the photographs. Conversely, if there are any blue stars they will come out brighter than their eye magnitude. Now, if we take as our standard the magnitudes as apparent to the eye, we shall find all the stars photographed either equal to the eye magnitude or above or below it. Where the actinic light is in excess the stars will come out brighter; where it is the contrary the stars will come out less than the eye magnitude. At the centre of the plate the stars come out as dots; at the edges as ovals. But, as these ovals increase in proportion to their distance from the centre, there is no difficulty in applying a correction, and the stars can all be reduced and compared with their known magnitude.

Early in October, assisted by Mr. W. H. St. Q. Gage, F.R.A.S., and Mr. W. L. Stubbs, I made some experiments with a rough equatorial stand on which was mounted a camera with lens of 2½ inches aperture. Our instruments were so rough that we did not succeed very well. However, some stars were photographed in Andromeda. Later on in the month we succeeded in obtaining two plates—one of the Constellation of Cassiopeia, the other of a portion of Taurus, containing Saturn and the Pleiades. The exposures were long, being one hour and twenty minutes and one hour and thirty minutes. The plates used were the Withington dry plates.

The results of these plates were communicated to the Liverpool Astronomical Society, at their meeting on the 12th of November. On the Taurus plate there are one hundred and twenty stars. Of these the little Asterism of the Pleiades furnished forty-one. From the two plates sixty-eight stars were reduced and compared with the eye magnitudes as given in the catalogue of Heis' *Atlas Cœlestis*. Of these, twenty-two show differences which we believe to be real. Nine belong to class A (stars where the actinic light is apparently greater than the eye magnitude), and thirteen to class B (stars where the actinic light is apparently less than the eye magnitude); so that about one-third of the total number show divergence from the eye magnitude. As might be expected this produces a very considerable change in the aspect of the stars, and on the plate the constellation of Cassiopeiæ, which is well known from its curious W shape, becomes altered; for Alpha, which is the second star at the bottom of the W, is greatly reduced, while Kappa, the third of the top stars, is equally increased in magnitude. Two stars known as Upsilon One and Upsilon Two, which appear to the eye of the same brightness and of the same colour, come out on the plate—one very considerably less than the other. In both plates minor changes of the kind are very noticeable. On the Taurus plate two stars of equal magnitude and equal colour come out a magnitude and a-half different.

As regards the planets, Saturn was photographed in the Taurus plate. At present we can only go upon the evidence of this single plate; but, from a very careful comparison, there seems little doubt that Saturn's reflected actinic light is only equal to that of the star named Eta Tauri.

When we consider the important part chemical light plays in the vegetable world we shall see at once how extremely interesting the question of actinic star light becomes. If the actinic light in the sun was greater or less than it is, remarkable changes would be produced in the world around. When a plant grows in the dark, its leaves are colourless. A very simple instance of this occurs in our every-day life in reference to celery, which, if not banked up and protected from light, becomes bitter, while the colour is altered to red. On the other side, the experiments of Dr. Siemens in forcing plants under the electric light have shown what an effect the increase of actinic light has upon plant life. Indeed so strong was the action that it was found necessary to shield the plants by placing a globe of glass round the light, otherwise they were killed by its intensity. The question as to whether other worlds are inhabited like ours has ever been a favourite one; but now, by the application of photography, we may produce new evidence, if we can determine the actinic light in each of the stars. Thus a new field of research is opened out, and doubtless it will yield a rich harvest in due course of time.

Special Observer to the Liverpool Astronomical Society.

DEVELOPMENT BY NAKED LIGHTS.

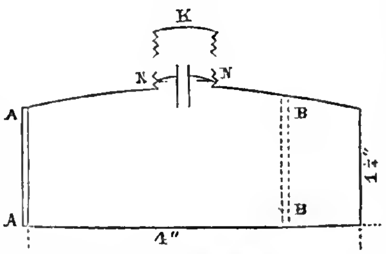
The necessity which exists for lightening the weight of passengers' luggage in travelling on the continent—also for lessening liability to damage by fracture—induced me, recently, to try what could be done in the way of abolishing photographic lanterns, and at the same time to conserve the power of working by a good light. In the copy of last week's Journal, to hand to-night, I see that for other reasons Mr. W. M. Ashman has been working in the same direction, and trying the influence of coloured flames.

Some ten years ago, at Kew Observatory, I saw the method in use, by Dr. Balfour Stewart, of developing photographic waxed papers by means of a Bunsen's flame primarily supplied with so much air as to destroy all the white light of the common gas used, and secondarily to then charge the flame with a soda salt, to give yellow luminosity. In travelling one cannot depend upon being able to invariably obtain gas, and, were it otherwise, the carrying of sufficient tubing, with mouthpieces of variable diameter, would prove a practical objection. Hence I fell back upon the plan mentioned by Mr. Ashman, of utilising the flame of a spirit lamp. Even for an ordinary photographic lantern, Mr. Donkin had to carry a metallic screw-topped lamp to Switzerland, and I surmised that by substituting alcohol for the oil, with or without the addition of soda, his lamp-glasses and frame ought to be unnecessary.

Dr. Balfour Stewart's plan was to suspend a bead of one of the melted salts of soda in the flame, on a loop of platinum wire, but the particular salt of soda he used I have forgotten; I remember, however, that the bead was when fused a liquid one, that it had then a tendency to drop off the wire, and required renewing with some frequency. My intention last week was to try the salts of soda all round, until in talking over the matter here with a chemist, Herr F. Brunck, of Züricher Strasse, Lucerne, he suggested the trial of biborate of soda, because that salt would form a bead on the loop considerably permanent either in the heat or in the cold, and yet would yield soda enough to "yellow" the flame, the quantity necessary for that purpose being but a trace.

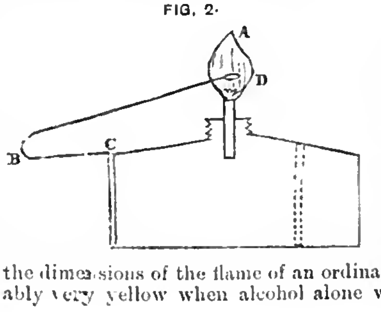
Accordingly a lamp was made for me in the town here, as follows:—

FIG. 1.



It was simply a lamp of brass, of the dimensions indicated in the cut, with the top K, to screw down tightly upon the neck N N, after which by the pressure of the top upon an india-rubber ring, the whole was made liquid-tight, so that the alcohol in it could be carried without spilling in baggage. Three fine tubes were soldered to my order outside this lamp; one of them is indicated by A A, another by B B, *fig.* 1, the third, of course, being the other side of the lamp. The small bore of these three tubes would permit the insertion of a somewhat fine wire—one thin enough to be bent into any desired curve by the fingers.

FIG. 2.



The wire, being bent into the form C B D, *fig.* 2, held in the loop D, the bead of biborate of soda in the spirit flame A. The shoulder B furnished a simple means of readily turning the bead D into or out of the flame A, for comparative experiments, as well as for regulating the elevation of the bead.

One evening I regulated the flame until it had about twice the dimensions of the flame of an ordinary candle. The light was palpably very yellow when alcohol alone was used, but on inserting the biborate bead, which was about as big as a cherry stone, it became yellower still. I then took a Fry's dry plate, and exposed different portions of it to the light, when free from biborate of soda, four different times, so that five sections of the plate had been acted upon respectively, for 3, 6, 9, 12, and 0 minutes. Next I inserted the biborate bead, thereby making the flame obviously yellower, and exposed the next plate from the same batch in the same way and for the same times. These exposures were all made at a measured distance of eighteen inches from the flame. Both plates were then developed at once in the same dish, with the same developer.

The result was unexpected. They both were much more acted upon than I anticipated from such a yellow flame, and no advantage had been gained by introducing the biborate of soda. That plate, indeed, was actually very slightly more intense than the other; but this may have been from a slight difference in the manufacture of the two plates, or from slight variations in the exposures governed by measuring them with the seconds' hand of a watch.

Spectroscopic examination of the two flames gave similar information to the photographic experiment. A very feeble blue and violet spectrum was to be seen with both flames, an intensely strong yellow one, and the light was fairly strong in the red. Yellow, we know, acts to some extent on bromide plates.

Although the light—in which I afterwards made no further use of the soda—thus fogged plates at eighteen inches distance, when exposed to it dry at right angles for a minimum of three minutes, the effect for this shorter exposure was but feeble; so that I saw at once that I could develope my plates by the light at double that distance with comparative safety.

The great point to remember in developing plates by bare lights is that the intensity of the light varies with the square of the distance. On this principle it was a common practice with me in the days of the old wet-plate process to print a transparency at from 6 to 15 inches from a candle, and to develope it at from 2 to 3 yards from the same candle; slips of cardboard at the edges prevented the wet surface of the hinder plate from touching the negative. I used to get sharp lantern pictures, with bare glass in the shadows, with impunity by this method.

All the negatives taken by me the last few days have in consequence been developed at more than a yard from a spirit lamp flame, taking care to let even that light fall on each plate as little as possible, and to let the sides of the dish generally keep the direct light off the film until the image was well out. The experience is satisfactory enough to probably prevent my having anything further to do with photographic lanterns when travelling. There is no more veil on the negatives than on the average of those I have seen developed by photographers in ordinary dark rooms appertaining to studios. The very feeble veil which exists would probably be removed by one of the usual clearing solutions. It is a great question how far the feeble veil in negatives is due to the light of the dark room; and, however dim this may be, those photographers who have not tested theirs by exposing a plate to its action for from three to fifteen minutes are not perfectly acquainted with the nature of their appliances in daily use. I was exceedingly surprised to discover in these experiments how much printing could be done on gelatine plates with a low and ghastly yellow light.

Still I am not satisfied, but wish to work with a bare and brilliant light; so I shall have to try the salts which give red and green flames to alcohol. Putting them in the alcohol itself is not an efficient plan; they (at least those generally known) are not volatile, they clog the wick, and, being much below the centre of combustion, have a minimum of influence on the flame. This is easily seen in the Christmas-party experiment of burning weak alcohol charged with salt. If the salt in the dish be below the level of the liquid, the effects are tame; but when lamps are put in, the upper portions of which are in the flame itself, the effects are exciting to unscientific observers. Of course there must be no other light in the room.

Probably Mr. Debenham's discovery will have little practical effect in preserving the good eyesight of photographers, the adverse influence being possibly due more to the low intensity than to the colour of the light. In the dark the pupils of the eyes dilate, and this is to be pre-eminently seen in the example of the eye of the cat, whereby pussy is able to see well in comparative darkness. Intermarriage between lady and gentlemen photographers would in a few generations probably produce a race able to see as well as cats in a feeble light; but this is not what is wanted, and it is not desirable to weaken the power of the eye in ordinary daylight. What is wanted is to first secure a light which does not act upon photographic plates, and then to use plenty of it.

Daylight will probably be found to be about the worst light to filter through screens to give this result; it contains such powerful chemical rays in the first instance. It will be best to make a start with a light emitting rays of low refrangibility, so as to have the minimum of high ones to abolish. A large Bunsen's-burner flame or a large spirit lamp flame, *plus* soda or strontium, with a thin screen of Mr. Debenham's cathedral yellow-green glass, would probably go far to solve the problem in permanent developing rooms, though for travelling I expect to use no more screens of any kind till one which does not break or tear is introduced. Why should not *ruby oil-silk* with Mr. Debenham's colours be made? The best developing light for bromide of silver I ever saw in a permanent studio was at the bromide paper-making works at Greenwich, and was founded on the principles herein laid down. The original light was that of a fish-tail gas burner turned up to full height, and placed in a kind of cupboard near the ceiling of the room. The door of the cupboard consisted of a very large area of thicknesses of orange paper. Large filtering surface, combined with considerable distance from the source of light, are elements of safety even with good luminosity. It was possible to work in any part of that room with comfort and without straining the eyes. A newspaper could be read with ease. Small lamps, as Mr. Donkin says, are bad in photography.

With brass lamps made as herein described there would be no great objection to add three steel knitting needles to the weight of the baggage, and the three needles inserted in the three tubes outside the lamp might serve to support the top of the camera stand, the centre of which would form an opening for the escape of the products of combustion. Then, if some enterprising man will but introduce a very flexible and transparent, non-actinic, untearable fabric, such as properly stained oil-silk, a conical cylinder of that substance, open at both ends, might be suspended over the skeleton framework just described. The objection to orange paper in travelling is that it is liable to tear and thereby give trouble at an inopportune moment; the objection to ruby glass is that it is always liable to breakage. W. H. HARRISON.

Hotel du Lac, Lucerne, Switzerland.

A WORD ABOUT STUDIO BUILDING.

FROM the advent of photography to the present time much has been spoken and written about this theme; nevertheless, I still cherish the hope that my small communication will not be found devoid of interest. Far be it from me to pronounce a decision regarding the different views of photographers as to the lighting power of flat and sloping roofs, over which there have been great disputes. On that question I offer no opinion, the real object of this communication being to treat of how a studio can be made to last for the longest possible time in good, substantial condition, and water-tight. The continual annoyances which are in store for the occupier of a badly-built glass house, and the inconveniences occasioned by repairs, are unfortunately only too well known, so that anyone may consider himself fortunate who is able by constantly-active attention to exercise his calling under a really water-tight glass roof.

It is well understood that two persons are required for every solid building—the technical man and the practical man. Who are or have these, almost without exception, hitherto been? For the first the builder or master-mason, and for the second the proprietor of the building, who is preferably the photographer himself. This would be all very well if these two gentlemen were always agreed and wished to understand each other, but that is hardly ever the case. In a word: the one could easily do what is required, but he does not, or, rather, will not take the trouble to understand what *is* required; while the other comprehends very well what is wanted, but cannot do it himself. His instructions and directions do not usually combine easily with the manner of execution customary in the building trade, and they are the rather allowed to fall to the ground, since an experienced builder must surely know best; and when he assures one that this or that drawback can be removed in some other way the photographer, who is no builder, is overruled, is fain to be persuaded that the builder's way is the right one, and the result is and remains the usual one—mistakes are made and are only observed when too late.

But there is a third person who might be taken into council but who is seldom consulted until it is too late, namely, the glazier. Unfortunately, he is nearly always left out of consideration, and is only called in when the building is nearly finished to complete, generally in great haste, the edifice. Any objections which he might make are now useless; for, even if he were acknowledged to be right, it is now too late to make any alteration, especially as a look at the sky is sufficient to convince him that haste must be made to get the roof on dry. Permit me, as a glazier of twenty years' standing, to relate my experience in this matter.

In the first place, it is especially necessary, in erecting the iron framework which is to support the glass, to insist (and this is still more imperatively necessary when the glass house is built out upon old roofs) upon the framework being independent of any neighbouring roof; that is to say, that even when the glass roof and the house roof are connected each part must have its separate supports. Above all, beams and rafters traversing both roofs are to be avoided; for, when persons walk about on the firm surface of the one, as often happens, that of the glass is shaken or bent, by which the outer skin of the putty is broken and water holes inevitably formed. The avoidance of these water holes is best attained by imparting to the putty a skin and maintaining it intact, which is best done by painting over the putty at least once a year with oil colour so as to prevent air and sun from acting upon it; for this water-tightness is, next to light, the chief requisite of a glass roof.

It is further advisable (though, unfortunately, this recommendation runs counter to the new plan of building) that the iron astragals should not be too massive, particularly in their breadth, as the greater the mass of putty which has to be spread upon it the more and the sooner will it dry up and shrink together, and consequently it will the sooner peel off from the glass. The dimension of astragal most suitable with a height of a centimetre and a-half is a width of three-quarters of a centimetre—that is, groove-width, but not much stronger. It is then also advisable that the width of pane selected should not much exceed twenty c.m., but rather that it should be somewhat less, otherwise the proportions will not be agreeable, the width being usually taken to be about two-thirds of the height of the pane. With a greater breadth this would not be practicable, as the individual panes would then offer too large a surface. The larger size would also render it more difficult to press the panes into the putty, whereby air-bubbles would be apt to remain in the latter, and these again are the direct causes of water holes.

I am speaking here of the common double glass; it is rather different when plate glass is used. There, there is no question of the surface, because the latter is perfectly even, and the glass presses firmly in by its own weight if the putty be merely prepared for it. It is of very special importance that the putty should be prepared with varnish and not with linseed oil, because the former dries slowly from without inwards, whereby an external skin is formed, which prevents any air from penetrating, and the putty always remains fatty. On the contrary, putty prepared with linseed oil puts on no skin, and is, therefore, very soon soaked off.

Then it is decidedly a great mistake when, as almost always happens, the expanse of glass is covered at the sides either with zinc or with roofing felt, &c. The real aim is quite missed if the intention be, by this means, to afford a protection against leakage. Under this covering surface dust and soot soon settle down firmly, and the rain-water trickles down and soaks in further and further, even beyond the end beams, and then the water-tightness suffers, and rot sets in, for it is never dry under the covered part.

Now, if the end beams be made relatively thicker and the covering material be laid in the groove before the glazing is commenced, so that the glass and putty are outermost, as at the middle part of the roof, this fault is not only cured but any repairs that may be required become very much more easily executed, while before they were almost impossible. Nearly every occupier of a glass-house will testify that the gables are the parts which suffer most from leakage, and that leak first of all. If the covering be of zinc, the precaution should be taken of going over it well several times with good oil paint before glazing, because zinc is known to be much less porous than iron. For the latter a single coat of paint is sufficient.

I have now to speak of an extremely-important point, with which many casualties are bound up, and which, unfortunately, no builder of glass houses seems to keep in mind, though it comes so near home to him. I mean an apparatus for securing the safety of all workmen who have to execute repairs, &c., upon such a roof; and yet it is a small thing to offer the person in question sufficient security, namely, if at intervals of two to three feet distance, upwards, a simple peg of iron be made to project for about a centimetre from each alternate astragal, so that the planks which the workman uses for walking upon might strike against them. When this is done it depends solely on the workman himself if anything happen to him, for the feeling of security lightens labour. Even the smallest movement of the plank on which one stands inspires fear and is sufficient to cause great injury and damage, as has repeatedly happened to myself. The thought that one is suspended at a height of five to six storeys appeals to one then in all its terrors.

I take this opportunity of inquiring why the police regulations only require these safety hooks or pegs upon slate roofs. Is it because it is more difficult to work upon a slate roof—which, as everyone knows, has always flat side-edges, and upon any and every part of which one can step or sit—than upon a glass roof, where there are only the slender iron astragals, which offer a most doubtful hold?

It is, nevertheless, a sad fact that this question has not been more minutely touched upon by the authorities, who have arranged so many protective measures for other purposes; and I believe there is no word of these small pieces of iron on the roof which are so small in size but have such important effects, though they prescribe such enormously-great solidity for the iron framework of the studio. As this precaution, therefore, seems to be still, as it was formerly, left to be voluntarily adopted, it would be well if all photographers or other traders who have occasion to build a new glass house would, as an act of self-help, insist upon the builder inserting these precautionary pegs, as it would then be easier for them to mount the roof either to clean the glass or the gutter.

Now, with regard to the great collections of dirt in the gutter: it is my opinion that a great deal of it is caused by the lowermost panes almost always projecting past the centre of the gutter, so that the rain water only washes one side of it, and that the outermost one; while on the other side it leaves untouched the dust, which easily accumulates under the projecting glass. Now, if the fall of the roof were so arranged that the lower edge of the lowermost panes should terminate just where the hollow of the gutter begins, then both sides of the latter would be equally washed, as the fall of the water would not be kept back, but rather would be led directly off the roof, thus the gutter would be less apt to become dirty or choked. If the iron pegs spoken of above as precautions for safety were there also, it would be but a trifling matter to give the gutter a frequent cleaning.

In conclusion: I beg all those interested in the erection of glass roofs to give the advice contained in the foregoing remarks a trial, both in their own interest and in that of the general public. There is no risk involved in the experiment, and I am firmly convinced that this method of construction would offer advantages exceeding all others, and would not be more costly. EMIL FUCHS.

—*Photographische Mittheilungen.*

RE-SITTINGS.

"STILL harping on my daughter!" It might appear quite superfluous to again revert to the subject on which I am treating, but for the fact that there is still a "thousand-and-one" varieties of opinion entertained on this same matter. Somebody says something to the effect that "Many minds make wisdom." Perhaps the source of my quotation is somewhat vaguely expressed, nevertheless it must suffice, as the excuse for my saying my little say.

Possibly no rule would exactly meet all classes of re-sittings; still, all things considered, I think it is usually best that a nominal fee—say just about sufficient to pay for materials—should be charged on each of these occasions, excepting where the manipulations or the photographers themselves are directly at fault. I mean, for instance, in the event of under- or over-exposures, imperfect lighting, blemishes, unsteadiness, and bad positives or expressions.

Of course, these defects are supposed to have no right to exist, and then free re-sittings should be courted, even for the photographer's own credit; but where the portrait is photographically satisfactory and the objection resolves itself into almost a question of taste, or even ordinary expression, then, certainly, I would conclude that a fee should be charged, alike in fairness to other customers and to secure the photographer from pecuniary loss through faults that are not his. Furthermore: it prevents those people who re-sit just through sheer wantonness from bothering photographers—people suffering from that melancholy complaint of having "nothing else to do;" and, however much may be said about some sitters being glad to get the operation over, yet I know from personal experience that there is still a fair percentage who eagerly seek this means of killing time so long as the entertainment is free of charge.

Let me state why I think it only just to all clients that re-sittings should be charged for all round. We may accept it as indisputable that a commercial photographer arranges his prices with a view to leaving himself at least a fair margin of profit. Then, if this profit be sufficient to include the expenses of a free re-sitting, certainly the majority of his sitters—those who are content in the first case—pay for what they do not get; or, even if the profits are such that re-sittings were to make the individual order a losing one, yet the surplus must come somehow, and the other clients are still, more indirectly, paying towards the extra work for that particular customer.

Another matter, on the ground of consistency, I venture to take exception to—the system so frequently adopted by photographers of destroying the first plates when re-sittings are given. It smacks of a greater feeling of independence than may be made a rule to indulge in in these latter days of photography. It seems to me very like seeking redress from the doubtfully-congenial task of punching one's own head! Satisfaction to the customer and gain to the photographer certainly go hand in hand, and all the profession will be able to call to mind many cases where the client, although desiring to be reasonable, has only become contented with the first proof by the time it had been compared with one from a second sitting—not, I may hasten to add, only due to the first picture being bad and the second one worse, but because they invariably find that the representation of their features is different to the hazy and too favourable impressions which it seems to be inherently natural that they form on the subject themselves; and this impression has to be gradually rectified by the combined influence of the "likeness growing on them" and the approving expressions of their friends.

In the event of this by no means uncommon revulsion of feeling I fail to see any advantage the photographer enjoys by the first negative being destroyed. Nor can I agree that the conditional offer to keep the negatives exactly meets the requirements of the case; for it is in every way probable that at that particular moment the client may really not care for the proofs, and be quite willing to have the plates destroyed if the photographer be so injudicious as to suggest it. It appears clear to me that the preserving of all negatives, coupled with a reasonable extra charge for such re-sittings as I have enumerated, is still the most rational means of fair compensation all round. There is no unjustness to one client through another having extra positions submitted, and the photographer increases his chances of receiving a good order proportionate to the extra possibilities of the individual sitter being satisfied.

While we endeavour to frame laws for our protection from imposing demands, still the sitter should always have "the benefit of the doubt;" and I cannot too forcibly remind all photographers, who respect themselves and their profession, of the every-day increasing necessity to avoid palming off indifferent work. The education of the general public to better photography is gradually but surely progressive; they will no longer continue to tolerate the "soot and whitewash process," nor any of the glaring defects that used to be either unseen or looked upon with a lenient eye as incidental to a new discovery. In these days of ultra-keen competition, if we do not harken to reasonably just complaints the rival establishment near by will do so, and farewell the patron.

I trust it is understood that I do not advocate fawning to clients; far from it. If their objection be decidedly unreasonable and the complaining person be obdurate on the matter of making further payment for extra sittings, then let him or her go. No photographer should entertain the idea of remedying an evil which possibly does not exist, and in genuine cases of this kind he will be most respected in the end, even by the grumbling customer who respects himself. But if there be really cause for exception to be taken to his work, and the photographer is confronted with it, then so much the better ultimately for both him and his profession. The same principle which governs necessity as the "mother of invention" forces the compulsory demand for better work to most naturally expand the elastic-like resources of our art-science; and it is this always increasing requirement more than all else besides that is gradually raising photograhy from out of the slough of mediocrity in which it has been so deeply embedded.

I "kinder calculate" that the Editors of the Journal will be comparing the length of my remarks and the limit of their space with not too-friendly-disposed feelings, so I shall show the better part of valour and retire. Let me conclude with the statement that one of the best means I know of to enlist the sympathies of the operator with the whims of his model is for the said operator to have an occasional negative taken of himself. He may *say* that the resulting portrait does him every justice, simply because he feels some amount of diffidence in giving vent to the same stale objections which he has "pooh-poohed" over and over again in the case of his clients. Nevertheless, in his heart of hearts, the possibilities are that he is wondering how the short-sightedness of his friends can make them admire such a caricature on the classic lineaments of his well-proportioned physiognomy. Nor is he apt to look upon those sitters who show occasional indications of unsteadiness during exposure as quite such unmitigated dunderheads after he has himself spoiled some two or three impressions in succession from the same cause; indeed, I am not prepared to state but he then begins to conclude that unsteadiness is due to some finer sensibility of nerves than those possessed by such common people as present an unflinching front to the camera.

LYDDELL SAWYER.

AMONG THE SOCIETIES.

In the course of a discussion on the employment of green glass in the operating-room, and which took place at the London and Provincial Photographic Association, Mr. A. Haddon asked a question as to how it was to be accounted for that leaves of trees make an impression in the camera if green light be so inactive in the developing-room. Upon Mr. Debenham replying that leaves of trees reflected a great deal of white light as well as green, Mr. Haddon wished to know why the leaves did not come out upon an iodide plate as on bromide if the white light acted. Mr. Debenham spoke of white *as well as* green light, and it is just because the iodide plate is impressed only by the former that the results as regards foliage were, as a rule, so inferior to those obtained with bromide.

An addition has been made to the practical applications of balloon photography, in the shape of the camera exhibited by M. Triboulet at the last meeting of the Photographic Society of France. When a panoramic or general view of a district is required for military or other purpose a captive balloon is employed to carry the photographic apparatus, the exposures being made by electricity. But instead of taking a series of successive pictures—which, in consequence of the motion of the balloon, renders necessary some special means of marking the position of the camera at each picture—six cameras are employed, and the exposures made simultaneously, thus securing at one *coup* a complete panorama. If a ground plan be required, an additional camera is worked from the bottom of the car.

At the semi-monthly meeting of the Photographic Society of Great Britain the chairman made a practical suggestion in connection with lantern slides, namely, that they should be printed upon quarter-plates instead of upon the usual $3\frac{1}{4} \times 3\frac{1}{4}$ size, in order to allow sufficient room for a description that will be legible in the darkened room. Mr. Sebastian Davis's experience during the series of lantern displays in connection with the Society's exhibition has, no doubt, led him to proffer this advice. It may be remarked that the Woodburytype slides of the Sciopticon Company are made this size.

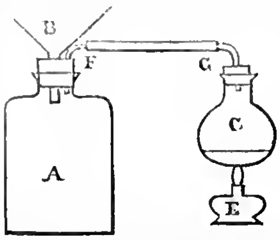
DR. STOLZE ON THE FIXING BATH FOR THE EMULSION PROCESS.

In the *Wochenblatt* Dr. Franz Stolze writes regarding the treatment of the fixing bath in the emulsion process:—The question of how emulsion plates should be fixed is coming more and more to the front. Though some maintain that the use of freshly-prepared hyposulphite is absolutely necessary, yet the results of theoretical and practical investigation seems to lead to the conclusion that while the fixing bath still contains enough of hyposulphite of soda to dissolve the haloid salts of silver quickly and energetically there is no danger in using it. That one must wash the plates thoroughly cannot be recognised as a sound objection, since that is also necessary when a fresh bath is used.

If there be, then, nothing respecting the permanency of the emulsion plates to be urged against the continuous use of the same fixing bath which is only occasionally strengthened, the question arises whether on other considerations it is advisable to do so. The benefit of using an old fixing bath is twofold:—First, there is its increasing strength, and then there is the possibility of recovering by suitable methods the great quantity of silver contained in it. He who knows what quantities of silver are gradually consumed in the emulsion process as bromide of silver—and that only a small part of that quantity is reduced in the developing bath, while the pridcipal reduction takes place in the fixing bath—will not lightly value the last circumstance. But when the same fixing bath is used continuously for a long time, and is only strengthened when it requires it, one wholly renounces the possibility of recovering the silver and rather carries the quickly-saturated solution on to the washing water, where it is lost. Now, if one wish to profit by both of the advantages indicated above, he must strike out a middle path which will lead easily and surely to the desired goal. If one only uses a fixing bath as long as it works easily and willingly, and replaces it by another as soon as it begins to work sluggishly, it will be easy to recover the silver from it. But then the newly-made-up bath, until it has been some time in use, exerts no strengthening, but rather a weakening, action. This drawback, however, can easily be removed if about a quarter by volume of the old bath be retained and added to three quarters of the new bath, just as many photographers do with the positive fixing bath. The bath then never behaves towards the half-tones like a perfectly new one, and yet one can recover the whole of the silver.

The next question that presents itself is—How can the silver be best recovered from the old bath? Perhaps the most generally-adopted of all known methods is precipitation with sulphide of potassium; and where it is a question of a quick and sudden separation this method has the advantage that the sulphide of silver falls in large flakes, and settles down very quickly. But for many studios this procedure possesses a great disadvantage, which not only renders it troublesome and inconvenient, but also dangerous to the other preparations; that is to say, where this operation cannot be carried out in the open air, but has to take place in closed apartments, the greatest precautions are required to protect silver baths, sensitive paper, emulsion plates, &c., from the action of the sulphuretted hydrogen gas given off. I would, therefore, call attention to another method by which the silver can be as completely—though more slowly—precipitated, and in the metallic state. Dr. Lagrange has already recommended ferrous oxalate developer for this purpose, and for this use it was recommended in the *Wochenblatt* that it might be made from cheap chemicals, even though not absolutely pure. In spite of that this method still seemed too expensive, until the idea occurred to me of using developer—either ferrous oxalate or pyrogallic—which had already served for developing plates. The former is at present *generally*, and the latter *always*, thrown out. Yet, since but a small part of their deoxidising power is exhausted, though they are no longer usable as developers, they were at hand to try whether they could not be serviceable for the present purpose. The experiments made succeeded beyond expectation. In every case, even when a great quantity of sodium sulphite was present, the developer acted excellently. The silver was completely precipitated in a few hours, and could then be separated by filtration from the mother-ley. I arrange matters as follows:—As soon as my fixing bath begins to work sluggishly, I pour three quarters of it into the stone jar in which it is to be precipitated, and every time I develope a plate I add the used developer also. It is not long until all the silver is thrown down. When any work to speak of is going on this will take place in a few days, a fact of which one can easily be convinced thus:—When you think that all the silver has been thrown down, take a little of the clear liquid from the upper part of the jar and put it in a test tube with some liver of sulphur; if there be no longer a precipitate, then all the silver has been thrown down and the liquid can be decanted off, leaving room for the next bath to be poured in to be precipitated when it is saturated.

Whenever there is enough precipitate collected at the bottom of the jar it has to be filtered and washed. To accelerate as much as possible this very wearisome work, I advise the employment of C. Beckett Lloyd's filter, which is excellent for this purpose. In order to be able to use it for large quantities I have given it the accompanying form. Into the neck of a capacious bottle A a funnel B is inserted, as air-tight as possible, by means of a gutta-percha stopper rubbed with vaseline. Through the same gutta-percha stopper a bent glass tube is passed, which is connected air-tightly with the wash bottle C, containing water, by means of a gutta-percha tube F G. The water in C is brought to the boil by the flame of E, and the steam finds its way into the bottle A. As soon as the latter is filled and the steam comes out of the funnel put a plug of clean cotton into the pipe of the funnel, and remove the flame from under C. Whenever the steam begins to condense, if the precipitate in the jar be poured into the funnel B, it will be rapidly freed from the mother-ley, which will be energetically sucked down into the bottle A; a water pressure of 10 atmospheres being brought to bear upon it, while 0·20 of one is the most that one would otherwise find available. This fifty times greater pressure furthers the work easily and rapidly. When the mother-ley has all been sucked out pour in water and dilute muriatic acid, and, especially as it is easy to fill A with steam from C repeatedly, it is easy to obtain an unusually pure silver powder in B.



Of course the same apparatus serves for the filtration of chloride of silver, should one not prefer to reduce it also with old developers and then to treat it along with the soda residues. Whether, or in how far, it is possible to work up the silver powder so obtained into nitrate of silver I cannot yet say, but shall set experiments on foot. But without that the whole procedure is very simple and particularly valuable, because by the way of freeing it from the ley which can be so rapidly done here, the silver powder is at any rate pure enough to let the photographer know pretty exactly how much his ingot ought to weigh when smelted. For practical purposes I would recommend that the steam kettle C should be made of tin, as it would then be more durable and reliable, especially if it were made to end in a metallic tube without the intervention of a cork. It is, of course, evident that not only the fixing bath of the negative but also of the positive process may be precipitated in the same way and in the same jar. The whole process has the advantage of being self-acting with the exception of the filtration. I may here mention yet another use for the soda bath, by which all methods of recovering silver residues are reduced to this one. If, for instance, one has some useless emulsion, he only needs to press it as nodules into the fixing bath or to pour it in fluid. The bromide dissolves in the soda and is likewise reduced to the metallic state. In this way the boiling with acid, which is so disagreeable to most photographers, is avoided. Now, with regard to the soda bath: when in use the method recommended in the repertorium may be employed of always having two fixing baths in use and employing them one after the other, always making the last one the first, and replacing it by a new second one whenever the old first works slowly and has to be put into the precipitating jar. But with careful working I do not consider this modification *necessary*, though it gives very reliable results.

A METALLIC PLATE-BOX.

If there be one photographic appliance better known than another it is, we imagine, the grooved plate-box. In the early daguerreotyping days they were in a large measure formed of tin; zinc, too, was not unfrequently employed. Both of these are still occasionally pressed into the service of the plate-box manufacturer, although wood is almost universally preferred. Under what circumstances M. Antoine Lumière, of Lyons, sought to obtain a patent in this country, in 1883, for a grooved tin plate-box for holding photographic plates forms a problem we shall not attempt to solve. From the fact that the protection did not extend beyond the provisional stage we infer that he has thought better of his original intention. The lapsed specification is as follows:—

The invention consists of a metallic box, intended to contain previously-prepared dry plates for photographic purposes, and to preserve them from all exterior action of light, of humidity, or of any other agent which could injure them.

The plates are enclosed therein directly after their preparation, and can then be transported by sea and by land in all climates without having to fear any alteration.

The photographer can preserve them indefinitely in good condition. In travelling the boxes which have been emptied can serve for various manipulations, such as for washing the negatives and protection against dust.

The negatives which are not to be developed until later can be replaced therein, and carried home protected from light and from all other deteriorating influences. This box and its cover are constructed of tin plate or of other convenient sheet metal fulfilling the necessary conditions of solidity and inalterability.

The height of the box is a little less than that of the plates which it is to contain; these latter are held therein in parallel grooves formed of a corrugated sheet soldered to the lateral walls, which are thus strengthened. The four vertical faces are also strengthened by projecting ribs of various forms.

The cover is provided with a shoulder parallel to its edges, which limits its application to the box in such a manner as to cover without touching the upper edges of the plates which project above the box.

The plates are thus held perfectly without contact, and can be easily placed and withdrawn by their upper edge.

All sides composing the cover of the box are carefully soldered by the overlapping of one of them over each edge in such a manner as to render the whole perfectly tight.

The closing is effected by a sealing with cement, sealing wax, or any other material preventing the entry of light, covered, if required, with a band of cloth or paper.

MANUFACTURE OF COLOURED PHOTOGRAPHIC PICTURES.

Under the above designation Mr. Josiah Adams, Jun., of Liverpool, entered the specification of a patent which did not pass beyond the provisional stage. It is as follows:—

In colouring photographs on glass, unless the colour be in the glass itself, and the photograph on the face, it has hitherto been considered impossible to get a uniform tint to the background, as air gets between the white paper used as a backing and the glass, and causes deepened shades.

If a glue or other adhesive be used, the paper is darkened and a greenish hue ensues. Now, as photographs made on first-mentioned plan, commonly known as opal glass pictures or "opals," are very expensive, it has long been a great desideratum to obtain pictures in which the whiteness of the opal glass is combined with the cheapness of the transparent glass. In opal glass, too, the paint being between the eye and the photograph, the fine gradations of the photograph are obscured thereby, and it is very difficult to paint an accurate likeness without a sitter. In the transparent glass photographs the paint is behind the photograph, and is seen through it, so does not obscure the photograph, and need not be so accurate and artistically done.

My plan of operations is to place the photographic image on the back of the plate, then paint its outer surface either after varnishing or otherwise. When the paint is dry, coat the entire back with a mixture of oxide of zinc, gum, and balsam, or oxide of zinc and a drying oil. In place of oxide of zinc the sulphide of zinc may be used, if the colours used do not chemically decompose it, or other suitable chemically-neutral pigment could be used with either of these menstrua. While the gum—which can be gum copal, gum elemi, or other like transparent gum—is still wet, a sheet of pure white cellulose paper is laid on in such a manner as to avoid the enclosing of air-bubbles, and gently pressed against the photograph, so that the menstruum in which the oxide of zinc or other pigment is suspended shall penetrate the pores of the paper, and be thus by capillary attraction withdrawn from the surface of the photograph. The paper is allowed to dry on the plate, and as evaporation goes on on the outer surface of the paper, still more of the menstruum is withdrawn from the surface of the plate. The result is, when the whole has set, a clear, closely-adhering coat envelopes the surface of the plate, and an effect almost, if not quite, equal to opal glass is obtained. Instead of pure cellulose paper other bibulous material could be substituted; but it must be absorbent, not brittle, and absolutely neutral chemically. The bibulous matter in some instances can be done away with altogether. Thus, if a varnish menstruum be used it can be laid on thick, and, before setting, the outer surface repeatedly but gently washed with ether. The ether having a strong attraction for the menstruum rapidly draws it from the surface of the plate, leaving the pigment against the latter. The result, however, is not as good, as it is liable to scratch or rub off, and is but a poor and expensive substitute for the process already described.

" 10	Manchester	Mechanics' Institution.
" 11	Ireland	Royal College of Science, Dublin.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Society, held on Thursday, the 27th ultimo, the chair was occupied by Mr. A. Cowan.

Mr. W. M. ASHMAN said that it had been stated that the addition of mercuric iodide to the pyro. and soda developing solution had the effect of shortening the necessary camera exposure in the proportion of five to one. He had, therefore, experimented in the direction indicated, and, having prepared the mercuric solution as directed, he had added three minims to the soda developer, composed of saturated solution of washing soda one ounce, bromide of potassium two grains, and pyrogallic acid two grains. He showed three plates, one of which had been exposed for five seconds and developed for three and a-half minutes with his stock developer, containing two grains each of pyro. and bromide and two minims of ammonia to the ounce. The second plate had been exposed for twenty-five seconds and developed for seven minutes with the soda developer without the addition of the mercury; and the third, which was exposed five seconds, had been developed, with the iodide of mercury added, for a period of seven minutes. The second plate appeared to have been properly exposed, whilst the first and third (especially the first) were decidedly under-exposed. He believed that the addition of mercury did exercise an accelerating action, but not to the extent claimed. He thought the gain in speed was less than double.

Mr. W. E. DEBENHAM remarked that, although the first plate (that which was developed with ammonia) appeared less exposed than the one which had had the same time in the camera and been developed with soda and iodide of mercury added, it was much clearer in the shadows, and he thought that an equal amount of detail might have been brought out if the development had been pushed to the same extent as with the soda plate. The ammoniacal developer which had been used contained less ammonia in proportion to the bromide and pyro. than was usual when it was desired to bring out the details of an under-exposed negative.

Mr. A. HADDON said that the soda developer gave a yellow colour to the negative. This might be temporarily removed by acid, but it returned when the acid was washed out of the gelatine.

The discussion then turned upon the use of a solution of mercury in iodide of potassium as an intensifier for negatives, and Mr. A. L. HENDERSON said that in the collodion times when a negative so intensified became yellow, it was blackened after thorough washing, by being flowed over in the light with a plain solution of pyrogallic acid.

Mr. HENDERSON then showed Mr. Starnes' lamp, which had been altered, in accordance with a suggestion made at the last meeting, by being painted chrome yellow on the reflecting surface, and fronted with green glass. In this state he had exposed a plate giving 24 on Warnerke's sensitometer quite close to the lamp for times varying from thirty seconds to two minutes. On the longer-exposed portions there were distinct indications of the action of the light. The light was very good for working by. At two yards from the lamp he could see well to coat plates.

Mr. H. S. STARNES said that on the previous evening a plate of Mr. Henderson's make, giving twenty-four on the sensitometer, had been exposed in portions for periods of from one to fifteen minutes, at a distance of two feet three inches, without giving any deposit on development.

Mr. W. COLES showed a much faded photograph which he had to copy, and inquired whether anything could be done towards restoring it.

Mr. HENDERSON suggested that it should first be copied in its present state, lest it should suffer in the attempt to restore it. He would after that try immersion in bichloride of mercury, followed by washing with lime wash. If ammonia were used it dissolved some of the silver. Some time since he had succeeded by converting the image into iodide, and then developing it with pyro. restrained by citric acid. Returning to the subject of dark-room lighting, he (Mr. Henderson) believed that the solution of the question would be found in the use of light of two colours, green and red, thrown upon one screen, which would serve as the source of illumination.

It was mentioned that on the 10th January Mr. Ashman would deliver his lecturette *On Printing*, and a resolution was passed that at all future meetings the chair should be taken punctually at eight o'clock.

PHOTOGRAPHIC SOCIETY OF BERLIN.

THIS Society met on the 6th November, when the chair was taken by the president, Dr. Hornig.

The CHAIRMAN intimated that he had received a communication from Professor Bruno Meyer, giving examples of the comparative worthlessness of the protection afforded to photographers by patents and copyright.

A short discussion followed, in which Dr. Eder and Baron Schwartz-Senborn took part.

Two sets of articles competing for Voigtländer prizes were received, namely, a set of carbon-printed lantern transparencies and a collection of enamelled photographs upon dials, &c.

The Chairman called attention to the objects exhibited.

Herr CH. SCOLIK remarked that he had been induced, by an advice by Mr. A. L. Henderson, in THE BRITISH JOURNAL OF PHOTOGRAPHY, on the preparation of gelatine emulsion with small quantities of bromide of silver, to make some experiments which led him to the conclusion that good results could only be obtained by observing the minimum of bromide of silver already indicated by Dr. Eder. He thought there was sometimes a tendency to use too small quantities of silver salts.

Lieutenant DAVID showed a wooden press (with a lever action) for gelatine emulsion, also a digesting apparatus.

A letter from Herr Eckert, of Prague, was read, in which he described a simple method of partially strengthening or reducing gelatine negatives.

A model of a dark slide in tin or sheet iron, recently patented by Herr Madar, was also shown. It combined lightness with greater stability than some of the cardboard slides that have recently been in use.

A collection of phototypes from the studio of Herr Studders, of Liepzig, and of autotypes from that of Herr Galiard, of Berlin, were handed round for examination, shortly after which the meeting was adjourned until the 11th December.

Correspondence.

BRISTOL INTERNATIONAL EXHIBITION.

To the EDITORS.

GENTLEMEN,—In your last number Mr. E. Dunmore makes some observations in connection with the late Pall Mall exhibition, attributing certain shortcomings to defective organisation, and instituting unfavourable comparisons with the Bristol Exhibition. I believe he stands as a successful exhibitor in connection with the latter, and when this is the case the defective organisation of exhibitions generally are seldom heard of, the success or otherwise of an exhibitor making all the difference. I will, therefore, with your permission, say a few words in connection with the Bristol Exhibition from an unsuccessful exhibitor's point of view, in the hope that, by drawing attention to certain sins of omission and commission, they may, as far as possible, be avoided in future exhibitions, both at Bristol and elsewhere.

First, then, the Bristol Exhibition, from its international character, now occupies the unrivalled position of the finest and, possibly, the most important in the world, the exhibits in the present instance amounting to the enormous number of *nine hundred*. From this it will be at once apparent how unreasonably small and inadequate to meet such circumstances the award of "thirty" medals presents itself, and the consequent injustice many exhibits must suffer in consequence; for it is certain there must be no mean proportion of equally meritorious productions with those selected for special distinction, but which, in the absence of a sufficiency of prizes, must of necessity go unrewarded. With so remote a chance before them of being placed among the favoured few it would not be surprising if the exhibits become less in the future; if economy has to be considered, then diplomas of honour would answer the same purpose as the more expensive medal.

Secondly. This exhibition, like most others, is held under the auspices of an "Amateur" Society. The ranks of this section of photographers are becoming so large and extended as to bid fair to outnumber their professional brethren, if, indeed, it be not already an accomplished fact; and yet it is only necessary to glance down the prize list to be struck with the fact that nearly the whole of the prizes have been awarded to professionals. I may be wrong, but I do not recognise a solitary half-dozen "amateur" names. Two of these specially-favoured ones are, I note, officers of society, but, I have no doubt, they have well earned their medals for all that. If it be a fact that the professional element is really so far in advance of the amateur as to thus beat it all round, and, in fact, shamefully out of time, then, in justice to amateurs, let all future organisers of exhibitions note the Bristol result, and provide an amateur section, letting each fight his own battle on equal terms. Then honour will be given to whom honour is due.

Thirdly. Again referring to the prize list: it will be seen that a large number of medals have been monopolised by pictures well known and already medalled or exhibited elsewhere. If judges are *not to know* who the author of an exhibit is until after the award, then the extreme folly of placing such among pictures that are really unknown, never having been hung on the walls of an exhibition before, is apparent. To prevent any element of distrust arising, and in justice to both judges and exhibitors, a special class, with its medal of honour, open only to medalled pictures, would not only meet the case, but would render the honour thus won of double value.

Lastly. Every jury, to command universal confidence, should be essentially representative in its constitution, comprising professional and amateur and artistic elements, neither predominating unduly. There is always a praiseworthy emulation for mastery between the professional and amateur, neither caring to be publicly beaten by the other. There are, consequently, certain opposing interests at stake, and the artist would supply the balance. Until this plan is adopted, amateurs will naturally feel aggrieved when professional judges award the premiums to professional exhibits, and especially so when the authors must, to a great extent, be known by their works.—I am, yours, &c., AMATEUR.

December 31, 1883.

To the EDITORS.

GENTLEMEN,—In your last issue Mr. E. Dunmore writes, complaining that of two pictures sent to the late exhibition in Pall Mall, by an exhibitor *whose name was unknown to the hangers* (the italics are his), one was rejected and the other, after the glass had been smashed, was "ignominiously floored," and assumes, because these pictures have just been awarded a medal at Bristol, that they ranked amongst the *best pictures* exhibited, whilst "average work" monopolised the "best positions," simply because the exhibitors were known and favoured, to the disadvantage of the clever unknown. What a very unfair assertion to make! Surely Mr. Dunmore knows that, with few exceptions, the pictures lately exhibited in Pall Mall were unnamed in front; and surely he must also be aware that many pictures hang in Bristol unnoticed by the judges which have received medals in Pall Mall! Where, then, is his argument?

Throughout his letter Mr. Dunmore *positively* asserts that the two illused (?) pictures were, without doubt, of the best shown in Pall Mall. Except for this I should have thought they were his own; but if they were he would not be so egotistical. No! they cannot be his. Whose were they, then? There's the rub! Some youthful and experienced brother, brimful of modesty or so doubtful of the qualities of his work that he feared a wigging for his intrepidity in daring to mix them up with that of others? It would, indeed, be interesting to know more of these strange intruders, and the subjects they depicted.—I am, yours, &c., BRISTOLITE.

December 31, 1883.

ALBUMEN IN GELATINE EMULSIONS.

To the EDITORS.

GENTLEMEN,—Can any of your readers inform me to what extent albumen or other colloids can be added to gelatine emulsion without impairing any of its good qualities? The cause of frilling and of the curling up of sensitive gelatine sheets, when not supported by glass, is the unpleasant property of gelatine of expanding and contracting immensely when absorbing different liquids. The want of good blacks and shadows with all the gelatino-bromide papers I have seen is also largely due to the thick and spongy nature of gelatine films, so that the picture is not all on the surface, but sunk to various depths in a spongy stratum.

In working for illustrated newspapers I cannot well wait several days, sometimes a week, for local photographers to copy my negatives on paper, and am unable to find anything pictorially satisfactory, not on glass, which can be printed by superposition by candlelight, and finished straight off with the same developing solutions used for my negatives, although those solutions will develope good lantern pictures free from stain.—I am, yours, &c., W. H. HARRISON.

Hotel du Lac, Lucerne, Switzerland, Dec. 31st, 1883.

EDINBURGH PHOTOGRAPHIC SOCIETY.

To the EDITORS.

GENTLEMEN,—With reference to a paragraph in last week's issue, regarding a paper read by me before the Edinburgh Photographic Society on December 5th last, I beg to state that all the photographic conveniences mentioned were my own inventions, with the exception of the bicycle saddle, for which I gave Mr. Marshall Wane (my employer) due credit at the time.—I am, yours, &c., WM. CROOKE.

21, *Salisbury-road, Edinburgh, December* 31*st*, 1883.

PHOTOGRAPHIC SOCIETY OF IRELAND.

To the EDITORS.

GENTLEMEN,—In the report of the Society's meeting, and of the paper read at that meeting, on the 14th December, 1883, by an error the name of Mr. J. McGhie was substituted for Mr. J. H. Halvey. Will you kindly, in justice to Mr. J. H. Halvey, make this correction?—I am, yours, &c.,

Dublin, January 1, 1884. CHARLES W. WATSON, *Assistant Hon. Secretary.*

BRISTOL INTERNATIONAL EXHIBITION.—AWARD IN CLASS IX.

To the EDITORS.

GENTLEMEN,—Permit me to send you the following resolution passed by the Council of the Association with regard to the above award. For the clearer information of those interested, I may say that the regulation for Class IX. reads thus:—"A silver medal for the best enlargement of any subject and by any process, *provided it be the work of the exhibitor.*"

Mr. W. F. Donkin inadvertently omitted to state that the enlargement exhibited by him was not his work when sending his exhibits, the result being that a difficulty now arises; and with much regret the Council feel that the least unsatisfactory course is the one they have adopted.—I am, yours, &c., H. A. HOOD DANIEL, *Hon. Secretary.*

Academy of Arts, Queen's-road, January 2, 1884.

Resolution.—"That in consequence of Mr. W. F. Donkin having disclaimed the medal awarded to him in Class IX., *the enlargement in question not being his own work, but that of the Autotype Company*, and the conditions of exhibition in this class thereby not having been complied with, the Council, with reluctance, feel compelled to withhold the medal."

Notes and Queries.

WILL any reader oblige me with a few hints as to the way by which the "ink photos." of Messrs. Sprague and Co. are produced? If I knew how the texture or grain was obtained, I think I could manage the purely lithographic portion quite easily.—A. P. F.

KINDLY answer, through your next issue, whether a name for a new style of picture can be registered—the name to become the property of the party registering. Also, if the name of a particular firm can be registered, and, if so, the probable cost in both cases.—T. A. H.

I HAVE an astronomical telescope with a five-inch object-glass. Prompted by what I have lately been reading I have been trying it on stellar photography; but the chemical focus is so very far away from that at which the clearest image is seen that I despair of success. I have been told there are some rules for effecting the requisite adjustment, and would feel greatly indebted to any one who will aid me with information.—(Rev.) GEORGE MORSE.

G. S. ROBERTSON.—A curious query respecting a point of law is stated by by our correspondent. We give it in his own language:—"I am very desirous of illustrating a forthcoming lecture by means of engravings which appear in a book recently published. But I am refused permission to photograph them for use as lantern transparencies. Now, if I purchase the book, have I not a legal right to tear out the engravings, paste them on glass, rub away most of the paper, and render what remains transparent with varnish, in this way obtaining my transparencies without any act of piracy on my part? And, further, by charging the engraving with iodine fumes, and imparting increased density to the lines by a process known to myself, doing this previous to the pasting on to the glass, do I commit an illegal act?——We refer this knotty point to any of our readers conversant with this phase of copyright law.

Exchange Column.

No charge is made for inserting these announcements; but in no case do we insert any article merely OFFERED FOR SALE, *that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a* NOM DE PLUME *be thought desirable), otherwise the notice will not appear.*

We will exchange two large gas meters for a double-action harp or good piano.—Address, G. B. BRADSHAW AND CO., 37, Oxford-road, Altrincham.

Wanted, Lancaster's *Le Méritoire* apparatus in exchange for two double dry plate slides, $7\frac{1}{4} \times 4\frac{1}{2}$, and focussing-screen. — Address, JAMES THOMSON, Tynet Mills, Fochabers.

I will exchange a lithographic press, by Straker, takes a stone 20×15, or large collotype plate, for a large portrait lens or an equatorial stand.—Address, W., 46, Haverstock-hill, N.W.

I will exchange a splendid walnut double stereoscope, containing forty stereo. views, for a 10×8 landscape camera, symmetrical lens, or offers. —Address, H. C., 16, Berkeley-square, London, W.

Wanted to exchange a complete artificial light apparatus to take portraits by night, for rectilinear or portrait lens or enlarging lanterns, or offers.—Address, W. GREEN, 23, Plevna-street, Hunslet, Leeds.

Wanted a 10×8 portrait lens and Kinnear camera for same in exchange for studio furniture, background, $\frac{1}{4}$-plate camera and portrait lens, burnisher, &c.—Address, ALEX. F. CLARK, 18, Glamis-road, Forfar.

I will exchange a pair of Newton's dissolving lanterns (mahogany cased), camera fronts, $3\frac{1}{2}$-inch double condensers, argand oil lamps and blow-through jets, all fitting lock-up case, for Ross' or Dallmeyer's lenses.—Address, F. J. SMITH, Clydesdale, Stoke-road, Gosport.

Wanted, 15×12 and 8×5 travelling cameras, in exchange for a 5×4 travelling camera, by Rouch, with four double and one single slides; a lady's silver watch, by Bennett, Cheapside, and other useful articles, or difference adjusted in cash.—Address, C. W. G. USHERWOOD, 5, Priory-terrace, Tonbridge.

PHOTOGRAPHIC CLUB—At the forthcoming meeting of this Club, on Wednesday next, the 9th instant, the subject for discussion will be on *Reducing Over-Dense Negatives.*

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

Photographs Registered—

Alexander Macdonald, Douglas Hotel, Brodick, Arran.—*Three Photographs of Ailsa Craig.*

Alexander Rae, Jun., Banff.—*Photograph of H.R.H. The Prince of Wales at Duff House.*

Thomas Newton Armstrong, Garrick-gardens, Glasgow.—*Photograph of Steamship "Meg Merrilies."*

Paul Stabler, 62, 63, and 64, John-street, Sunderland.—*Two Group Photographs of the Prince and Princess of Wales and Shooting Party at Wynyard Park.*

Notice.—*Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a* nom de plume *as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.*

M. P.—See inquiry under head of *Notes and Queries.*

F. W. Vollmar.—Much may be said in favour of both lenses. We make use of that most recently introduced.

Phil.—The collodion is too old. The pyroxyline has evidently become decomposed. Procure a fresh sample and make another essay.

B. P. Lascelles.—Husnik's work on the subject is the best you can possess. It is published in Vienna, and may be procured through any foreign bookseller.

S. Wyatt.—If the facts be as you state there can be no doubt whatever, even under the present law, that the copyright in the pictures is valid, and that it is your property.

R. B. Yeldon.—Try fusible metal. That may be procured so as to liquify at a temperature below that of boiling water. Any philosophical instrument maker will supply you with a small quantity with which to experiment.

Bevel Edge.—The only apparatus necessary is a mount cutting-knife, a straight-edge, a pair of compasses, and a blacklead pencil. Provide yourself with these and commence experimenting. The matter is simple enough, and requires but little practice.

Londoner.—Point out more definitely in what your difficulties in the collodion transfer process consist, and we will do our best to assist you. All we can gather from your communication is that, as you say, you are "in a mess." This is too vague a term for us to advise upon.

F. J. Cox.—We should advise you to purchase the canvas, ready prepared, from an artists' colourman rather than attempt to prepare it for yourself. It is a troublesome operation, and requires some technical knowledge. Are you aware that it is an article of commerce in rolls of several yards in length and of various widths?

A. Y. Z.—The markings are due to the cracking of the varnish. The only preventive we can suggest is to preserve the negatives in a dry place. If you sprinkle the negatives over with a little black pigment in fine powder—lampblack, for instance—and gently rub it over the film with the finger, the cracks will be filled up, and scarcely show at all in the prints.

Ajax.—There is no work published on the process, nor is one necessary. Woodbury lantern slides are made in precisely the same manner as ordinary Woodbury prints, except that glass is used instead of paper. If you are *au fait* with the production of prints on paper you will have no difficulty in making them on glass. No press, however, is necessary in the printing; all that is necessary is to press the glass on to the mould with the hand.

G. F. H. inquires:—"What form of development and intensification would you recommend for producing the most brilliant *wet*-plate negatives from engravings? I have some I wish to copy for enlargements, but have not had much experience in this class of work."——In reply: employ a rather old collodion, and a developer coloured from the presence of a persalt of iron. This condition is induced by dissolving the protosulphate of iron in hot water and allowing the solution to stand for a few days before using it. Tone with a weak solution of chloride of platinum.

Demarr.—1. You should have no difficulty in making the paper negative register. You must bear in mind that paper always expands more in one direction than it does in the other.—2. Surely you are in error when you say that "the area of the picture is enlarged when the stop is drawn out." If you examine it more closely you will find that it is the reverse of this.—3. Transparencies by the gelatino-chloride process are better than those by the gelatino-bromide process, for several reasons. The lights are purer, the shadows more transparent, and a much greater variety of tones can be obtained. Your previous letter did not reach us. We have reason to believe that several communications have miscarried during the past week or two.

Relief Experimentalist.—If your Woodbury films have taken over a week to dry there is little wonder that you failed to wash away those parts which had not been acted upon by the light. The reason is simple: the films, by being kept moist so long, had become spontaneously insoluble. They must be dried in a much shorter time than yours have occupied, otherwise they will be worthless. You will, at this season of the year, have to take advantage of the property which chloride of calcium possesses—namely, that of absorbing moisture—and place your films in a box at the bottom of which is a tray containing the salt. If the films do not contain too much glycerine, they should be perfectly dry in from twenty-four to thirty-six hours.

Hugh.—At the time specified we received the photograph now referred to, but have no recollection of any letter accompanying it. The strong contrasts between the lights and shadows are probably owing rather to the light than the quality of the plate. We judge that the picture was taken in strong sunlight with a clear blue sky. If this were so it would account for the want of definition in the shadows. We strongly advise the employment of a much larger stop in the lens. The maker of the plate upon which the negative was taken does not claim for his productions the highest degree of sensitiveness. The picture, notwithstanding the want of detail in the shadows, is quite interesting. With regard to ascertaining the strength of liquor ammonia: the specific gravity test, while one of the simplest, is also capable of giving results sufficiently accurate for practical photographic purposes. At page 254 of our Almanac for this year a table giving the strength of ammonia will be found.

A Hint on Developing Dry Plates.—We extract from our Almanac Mr. William England's excellent suggestions to amateur photographers:—These few remarks are more addressed to amateurs than professional operators, although the latter are sometimes rather careless in developing, with the result that they get stained and spotty negatives. A very important matter is to keep the dish perfectly clean. I prefer a glass one, although ebonite has an advantage in travelling. Marbling stains on the negative are caused by a scum forming on the side of the dish by repeated use, and on the developer being applied this comes off on the plate. I witnessed that in several studios lately, and on my telling the operator to thoroughly wash the dish with diluted nitric acid the plates afterwards developed perfectly clean. A brush called a 'painter's tool,' of a medium size, will be found very convenient for this purpose. Spots on the plates may arise from several causes, but the principal ones are dust in the dark slide. A clean camel's-hair brush passed lightly over the plate before placing it in the slide, and well dusting the latter, will cure this evil. Another cause of spots is air-bubbles formed on the plates during developing, which prevent the solution coming in contact with the film, and which thus causes transparent spots on the plate being fixed in the hypo. To obviate this, pass gently a clean camel's-hair brush over the plate during the development, if it be necessary. The above remarks seem so commonplace that I should have hesitated to make them, but several correspondents lately have called my attention to these matters.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician, *For two Weeks ending December 26, 1883, and January 2, 1884.*

These Observations are Taken at 8.30 a.m.

No. 1236. Vol. XXXI.—JANUARY 11, 1884.

NATURAL CLOUDS IN REPRODUCED NEGATIVES.

In two previous articles we have shown that it is possible to produce duplicate negatives which shall be quite equal to the original, and in many instances even better, and have given the details of the various operations necessary to secure this end. We shall now point out another direction in which a very decided gain is made in the operation of reproduction, and with the expenditure of a very small amount of trouble. We refer to the introduction of natural clouds or new skies into the duplicate negative.

It very frequently happens that a negative, though otherwise satisfactory, possesses a defective sky. This, possibly, prints too dark, giving a heavy effect to the picture, or it is marred by scratches, spots, stains, or other blemishes. It is possible to mask the sky and so make it print less heavily, and it is also comparatively easy to remedy the several other defects by suitable treatment of the negative; but this treatment and all this care has to be devoted to each separate print, whereas by the method we have to propose the trouble is got over once and for all by making a reproduced negative.

We need not dwell further on the advantages derivable from the adoption of this plan, nor stay to point out other possible applications of the same principle, but will proceed at once to the details. Presuming we have a negative of which the sky is in some manner defective—it matters not how—the first step is to produce a transparency, for which purpose the gelatino-bromide process must be employed. The directions given in our previous article will apply perfectly here, the object being to produce the best possible positive from the negative in question, ignoring entirely the sky portion. No attempt need be made to mask the sky nor to stop out any defects; for the sky, as it exists in the original, is simply obliterated —done away with—in the following operation.

The transparency, having been developed and fixed, is washed very carefully, and allowed to dry. It is not absolutely necessary that it should be dried at this stage, but we prefer that course for reasons that will be explained. Now prepare two solutions as follows:—First, dissolve separately, each in five ounces of hot water, one ounce of sulphate of copper and two ounces of common salt; when dissolved mix the two solutions, and, if necessary, filter. A second and weaker solution is made by diluting one part of this with five or six parts of water.

The transparency is now laid upon a retouching desk (or if such a convenience be not at hand it may be held against a window), observing that the sky portion must be downwards. This avoids any chance of the solutions running down over the landscape portion of the negative during the next operations. Now, with a fine camel's-hair pencil and the stronger of the solutions given above, follow the outline of the sky-line very carefully, leaving a margin of (say) one-sixteenth of an inch. Here is the advantage of the dry film: the solution spreads less, and it is easy to work almost into the intricate outlines of foliage with a little care; whereas on the wet film the copper solution spreads rapidly.

By the time this has been done the solution will have produced a white line wherever it has touched. Taking this as a guide, and with a larger brush, or a tuft of cotton wool, wash over the whole of the sky with the same solution until, when examined from the back of the glass, it presents an even white or greyish-white tint. Now wash for a minute or two under the tap, and re-immerse for a short time—a few seconds will generally suffice—in the fixing bath. Upon removal from the latter the sky will be represented by perfectly clear glass—presuming that the film has been properly washed between the different operations—except for the narrow margin left round the terrestrial portion.

This is now "tackled," and it is here that the only call is made upon the skill of the operator, though even at this stage but an ordinary degree of care is necessitated. Taking the small brush and the weaker solution, it is better to work slowly along the sky-line, gradually softening the remaining portion of the old sky if it should give a very pronounced tint; but this is rarely the case. Occasionally during the operation the larger brush, filled with the weaker solution, is passed with an undulatory motion along the whole sky-line, and in a few seconds the plate is plunged into water or held under the tap. This helps to prevent any formation of a too sharp line; but with ordinary care, and by proceeding in the same manner as in softening a wash of water-colour, the desired result is gained without any risk.

Should, by accident, the margin be overstepped, and the copper solution allowed to encroach upon the landscape part of the negative, wash the film and immerse the plate in a dish of developing solution—preferably ferrous oxalate—which will undo the injury. After again washing, the process may be resumed at the point where it was interrupted. Not the slightest deterioration occurs in this application of the developing solution to remedy a slip or an accident; hence no hesitation should be felt in at once putting the remedy into practice when the slightest cause arises.

If the various operations have been carefully performed the result will now be a transparency with a perfectly clear sky, into which clouds of any desired character may be introduced. These may be rubbed in with plumbago, or other artificial means may be adopted upon the transparency itself; but we decidedly recommend as preferable the use of natural clouds. These may be applied in the following manner, presuming, of course, that a stock of cloud negatives is at hand.

Clean a plate of glass in the ordinary way, finishing it off by polishing with powdered talc or wax solution; coat with collodion and produce a transparency of the desired clouds of the proper depth to suit the landscape transparency. When finished flow over the film a forty- or fifty-grain solution of gelatine, to which a little glycerine has been added to destroy its brittleness, and when this is dry strip the compound film from the glass. Place this in contact with the landscape transparency, and go carefully over the sky-line with a lead pencil, and afterwards with scissors or a sharp penknife divide the cloud positive at this line. Affix the proper portion to the sky of the transparency and proceed to make a compound negative in the same manner as has been previously described.

Another, though not so good, a plan is to make a positive silver print of the clouds, and having marked thereon with pencil the sky-line, to obliterate the clouds on that portion of the print which covers the landscape by means of the copper solution, followed by hypo. After washing, drying, and waxing, the paper cloud positive is attached to the transparency and printed on to a sensitive plate, as previously described.

In this manner cloud and other effects may be produced with an ease and certainty which are surprising, and the resulting compound negative obviates all the trouble and care which otherwise would have to be expended on each individual print.

PHOTOMICROGRAPHY.

In the plan adopted by Drs. Woodward and Curtis at the Army Medical Museum, Washington, a Silbermann's heliostat is arranged on a shelf outside, part of the window is closed by an immovable shutter, in which is a square hole to receive a movable shutter with an aperture of the same diameter as the short body of the microscope, which is connected to it by a sliding, light-tight tube. Another, worked from the inside, is made to close the aperture, outside of which is fixed the ammonio-sulphate copper cell. Below this is fastened a brass tube projecting outwards about thirteen inches, and carries at its end the microscope mirror, which can be adjusted from within the room by steel rods attached to it by ball-and-socket joints, and passed through the shutter. The microscope is placed on a shelf on the inner window sill. The camera and table, or base-board, at first used are dispensed with. The plate-holder is supported vertically upon a car that runs upon a tramway, laid correctly upon the floor for the distance of ten feet, and can be arranged at any distance upon it, a scale being laid off near to one of the rails. The image is first examined upon a white card, and the corrections of the objective made; then the card is replaced by a piece of plate-glass, the operator being seated behind it, and the final focussing made by means of a rod, and two bevel wheels, through one of which passes the long focussing-rod, connected with the fine adjustment of the microscope, by a silk band from a wheel, upon the edge of the shelf to which the rod is attached. A movable, yellow pane of glass allows of examining the sky, and the room is otherwise lighted by non-actinic light. Later the ground glass, used to prevent diffraction and interference lines when photoghraphing histological objects, was dispensed with, and a two-inch achromatic combination of about ten inches focus was used to condense the light from the mirror, the rays being allowed to diverge, as in the late Rev. J. B. Reade's plan, just before reaching the largest lens of the achromatic condenser. Sometimes the heliostat was dispensed with, and a large right-angle prism employed in the position of total reflection. This allowed of shorter exposures, and furnished equally good negatives, though with the trouble of constantly adjusting the illumination. The one-eighth objective was usually selected for anatomical preparations at from 200 to 500 diameters, but the preference was given to immersion lenses. For oblique light, in photographing delicate test objects, the light was directed from the mirror, so as to fall about three inches to one side of the centre of the stage, and reflected by a prism, set beneath the stage, at the angle needed to furnish the necessary obliquity, as thrown upon the object by an intervening objective. Dr. Woodward strongly advocates the use of specially-corrected object glasses, and states that, though the chromatic aberrations are neutralised by the blue cell, the spherical aberrations are not disposed of; and advises in the construction of such objectives that they should be tested by sunlight and the blue cell. Dr. Carl Seilers states there is no necessity for specially-corrected objectives when using monochromatic light. Professor Rutherfurd, of America, was the first, we believe, to suggest the construction of these objectives, and Mr. W. Wales made an one-tenth for him upon this form, the posterior combination being removable, and another back combination made to take its place for ordinary work. We have lately had an opportunity of testing an one-twelfth objective by Leitz, price five guineas, and can speak highly of its photographic qualities; but it required the most careful adjustment of the sub-stage condenser. We believe Dr. Woodward's plan is the most certain and correct. For further details see the *Catalogue of the Microscopical Section of the U.S. Army Medical Museum,* Part II., pp. 31-34, with three figures; also Dr. Woodward's article in the *American Journal of Science and Art*, and this Journal, October 12, 1866, pp. 480, and December 21, p. 607, 1866; also *Silliman's* and this Journal, October, 1871, *Monthly Miscroscopical Journal*, October, 1871, for his Report to the Surgeon-General, U.S.A.; and *Quarterly Journal of the Royal Microscopical Society*, January, 1872.

Dr. Sternberg—whose book, *Photomicrographs and How to Make Them*, was lately reviewed in this Journal, September 14th—when alluding to the operating-room, recommends the upper and lower sashes of a window facing south to be removed, and their places supplied by a frame, the right side permitting access to the heliostat arranged on a shelf outside, and the microscope to be placed, not in the centre, but as much as possible to the left-hand side. The heliostat governor (Woodward's, a tube with a ten-inch focus achromatic lens at the outer end, and at the inner one a space for the blue cell), is fixed to the frame, the axis corresponding to that of the microscope supported on a shelf, so "that the eye of the operator is on a level with the eyepiece of the microscope when he stands erect," which is the position preferred. The fine focussing is done by means of pulleys and cords worked at any distance from the instrument, a waxed linen thread being passed round a groove in the milled head, one end weighted by a small bag of shot, and the other end directed by pulleys to a framework *above the microscope*, and then to the spool, or key, which is fixed to the wooden frame of the movable screen. In this way the floor is clear, as a smooth piece of 2×4 scantling of a proper length to reach from the shelf to the opposite wall supports the screen. Dr. Sternberg suggests that beginners should work without a heliostat, and if the operating room be not sufficiently elevated to look out horizontally upon a clear blue sky, to incline the instrument 8° or 10° like a telescope; and that the microscope be placed on a shelf higher than when used in the horizontal position, to be reached by standing on a little platform, whilst the frame is suspended by a similar scantling placed with the same inclination as that of the microscope, its lower end being supported against the opposite wall. He strongly recommends this plan, even when not devoted to photographic use. A tube, an inch and a-half in diameter, slides in the shutter, and makes a light-tight connection with the sub-stage tube. The space between the microscope tube and the screen may be enclosed by a conical expanding bellows camera, if the exposure be long. He suggests two swing shutters to the camera—one of ground glass and the other of plate glass—so that they can be substituted the one for the other; or the former may be in a frame smaller than the latter and kept in place by a button, and removed when not needed. If the microscope face the sun, to prevent direct sunlight entering a sunshade tube, dull blackened on the inside, should project outside. A method is given for measuring. For obtaining fine black lines in the positive, silk or horsehair threads are stretched in front of the sensitised plate. By the use of a square diaphragm, one half of the plate can be covered whilst the other half is exposed; then this is to be covered by the diaphragm during the exposure of the other half, so that two pictures may be obtained for comparison on the same plate, and in juxtaposition, as blood discs of man and dog, &c.

In a paper by Mr. G. M. Giles (*Monthly Microscopical Journal*, January, 1876) is described a method to be used without a heliostat. He employs a large mirror four and a-half inches square, hung like a swing glass and adapted to the end of the base-board, so as to be capable of rotation in any direction by the use of cords, grooved wheel, and pulleys worked from the camera end. A large, three and a-half inches diameter and long-focus (ten inches) achromatic lens is employed as a condenser, for the purpose of procuring a large disc of light in sunlight illumination, and an alum cell, for stopping the heat rays. The holes in the diaphragm wheel, except one, are stopped with non-actinic paper. The wheel rotates loosely, and is used for making the exposure. The eyepiece is allowed to remain, "though seldom at the full ten inches." With artificial, paraffine, or magnesium light, the large condenser is dispensed with, and the ordinary achromatic condenser and mirror used.

In Mr. Walmsley's arrangement (for figures and description of which see *Journal of the Royal Microscopical Society*, page 557, 1883), with an ordinary expanding camera, there is a contrivance for focussing, which is stated to be of considerable delicacy, in use with the fine adjustment. The milled head of this screw has a groove cut in it, "around which a small cord is passed and carried through a succession of screw eyes on either side of the base-board to the rear, where a couple of small leaden weights are attached to its ends, thus keeping the cord taut. A slight pull on either side, whilst the eye is fixed upon the image on the screen of plate glass, suffices to adjust the focus with the utmost exactness."

Other methods of arranging the usual ordinary apparatus for photomicrography might be cited, but sufficient have been named to offer a fair selection of the most useful plans.

COMBINATION PRINTING.

In former times one of the principal qualifications of a photographic printer was his ability to produce from a negative with a defective background a print with one not only free from defects but also artistically graduated as regards light and shade. At the period to which we refer it may be mentioned few portraits larger than the old half-plate size were issued without a false background being introduced, and the print—which was usually on plain or what was called "salted paper"—being worked up to some extent in monochrome. As time wore on greater perfection in the manipulations enabled negatives to be produced in which the backgrounds were sufficiently perfect to be printed with the figure. Hence there was no longer a necessity for double printing, while, arising from the more extended experience of operators, finishing in monochrome was no longer required; therefore, salted paper and masked backgrounds practically became a thing of the past.

At the present time, if a masked-out background be required, it is generally that one figure only out of a group is desired as a separate portrait. Or it may be that when the original photograph was taken the portrait was only a secondary consideration to the other portions of the picture, but, owing to the changes wrought by time, it has become, at least to some, the most important, and they are therefore desirous to possess it in an isolated form. In cases such as this many modern printers are at a loss how to proceed when a salted paper print, with a masked background, or one printed from a second negative, is required. The result is a feeble print, on the back of a piece of albumenised paper, with a flat, even tint all over (as a background is produced) too often with a white line surrounding one part of the figure and a dark one the other. Such defects as these, entail upon the artist who has to finish the picture the greatest possible trouble to obliterate them. The print, also, is on the wrong side of the paper, which is very undesirable, as that always shows the web mark.

Now, the printing-in of a plain background is really a very simple affair after all, and this is the method usually adopted, or, we might say, used to be adopted. First, a print is made from the negative sufficiently strong to show the outline of the figure distinctly, then the figure is carefully cut out with a sharp penknife, keeping carefully to the outline. The two masks thus obtained are then exposed to light until they are thoroughly blackened. The background mask is now carefully adjusted on to the negative and secured in position with a few touches of gum, and the negative is ready for printing from. When printed, we have, of course, the figure merely with a white background only.

What is required now is to protect the figure from light while the background is being printed to the requisite depth. The plan generally followed in doing this is to remove the print from the frame and lay it on a board covered with black velvet, then to adjust the figure mask upon the printed figure, keeping it in position, when once adjusted, with a piece of plate glass. It is then exposed to light. Here some little judgment is necessary in shading, so as to produce artistic graduations, instead of the uniform flat tint one so often sees in what are termed "printed-in" backgrounds. The printing-in of a plain background is simple enough, and it only requires a little practice and ordinary care to accomplish it satisfactorily. However, the inexperienced often meet with a difficulty, namely, that they are unable to obtain an impression which does not show a palpable juncture, although the masks were, apparently, accurately adjusted alike on the negative and the printed figure. Frequently this arises from the opening in the background mask not being of the same size as that of the figure, although both were cut from the same print. This is owing to the expansion of the paper from moisture, which is often noticeable by the mask on the negative that was perfectly flat when first adjusted becoming cockled. It is manifest that if one mask be kept in the damp and the other in the dry, one will expand while the other will contract, consequently they will no longer fit each other or be in perfect register; hence, at least, one source of trouble.

At two of the recent meetings of the Photographic Club *Masking and Double Printing*, generally, formed an interesting and instructive topic of discussion, and at one of them Mr. Jabez Hughes described a plan adopted by the late Mr. Alfred Hughes for printing in false backgrounds, which obviated the difficulty arising from the expansion and contraction of the paper. It was this:—Instead of employing a paper mask, as just described, the background in the negative was carefully painted out for a quarter of an inch or so all round the outline of the figure; the remainder of it was then covered with a roughly-cut paper mask, or it might, if more convenient, be painted over with black varnish. After the figure had been printed to the requisite depth the print was removed from the frame, and its outline (on the print) was carefully painted, to the depth of about a quarter of an inch, with opaque body colour—lampblack being used. The remainder was then covered with a roughly-made paper mask. The print was now exposed to the light to print-in the background—being shaded and graduated as judgment and taste should dictate. In washing the silver out of the paper, prior to toning, the lampblack was removed, leaving the print none the worse for the treatment it had undergone. By this simple method accuracy of registration was ensured. Instead of printing-in a plain background one from a second negative is frequently required, and here greater judgment is necessary.

Many of our older readers will remember the charming little *carte* portraits, with landscape backgrounds, which were produced by Mr. Edge many years ago. These portraits were taken in the studio, and the landscape, from nature, was printed-in from a second negative. At one of the meetings referred to Mr. E. Dunmore explained the method by which this was accomplished, and which was as follows:—The portrait, a full length, was taken in the studio. The background, instead of being flatted in the usual way, was painted with ordinary glossy paint, and was shaded from a somewhat light to a moderately-dark tint, so that, when the negative was printed from, a portrait with a graduated plain background was the result. Different methods of masking the figure while the background was being printed were described, but this is the one finally adopted by Mr. Edge. After the figure had been printed, with the graduated background the impression was removed from the frame, and the figure painted over with gamboge sufficiently thick to protect it from the further action of light whilst the background was printing. The print was then placed on the landscape negative in another frame and printed to the requisite depth. The prints were now toned and fixed in the ordinary manner. In washing out the silver the gamboge was dissolved off, leaving the print intact, the same as in Mr. Hughes's method. One thing was specially alluded to and requires mention here, namely, that the landscape negative must be very thin and feeble indeed—such an one as it would be impossible to obtain a good impression from in the ordinary way, because if it were at all strong or vigorous it would, in this instance, be impossible to obtain artistic results, such as Mr. Edge's undoubtedly were.

This simple plan of combination printing might profitably be utilised now-a-days by portrait photographers for the production of (say) panel portraits in the studio, with backgrounds of interesting local scenery.

The term "combination printing" is a comprehensive one, inasmuch as it embraces not only the production of impressions, both in silver and carbon, from more than one negative, but also of transparencies, and the making of combination negatives containing portions of several others, all of which came under consideration during the discussion. We shall resume the subject next week.

CHLORINE, BROMINE, AND IODINE.

The experiments on the mutual reactions of the halogen elements by Paul Julius, described by us last week, deserve more than a passing notice, bearing, as they do, upon an important point in the chemistry of photography; and it will be interesting to remind our readers of some of the ordinary reactions of these three principal members of the group, bringing together some long-accepted modes of separating them and other interesting methods recently suggested.

The older chemical authorities used to give so-called "tables of affinities," in which various substances were classed in the order of the affinity they were supposed to possess for the body placed at the head of the table. Thus, for *metals*, the tables ran—O., F., Cl., Br., I, &c.; but modern chemistry has conclusively shown that such orders merely represent functions of a particular case, and that they are very liable even to be reversed under altered conditions. It is true that chlorine gas may, and usually does, drive out bromine, and that the latter again may displace iodine from combination; but it is also true, as shown in a most conclusive manner by Herr Julius, that the exact reverse of these reactions can be brought about when also the elements are employed in the gaseous form, and, indeed, that any halogen, if applied in excess, is capable of expelling any other halogen from its combination with silver.

To detect any one of these elements in solution the precipitation by silver gives results so characteristic that mistakes cannot readily be made; but when all three or the last two are found together the difficulty is very much increased. A well-known authority says—"There is no known method of effecting a separation of these elements" (bromine and iodine). This being the case, it is evident that the examination of a dry-plate film, for instance, or a sample of collodion, to ascertain its exact composition, may, perhaps, be considered a matter for the skilled chemist only; but to find out whether any or which of these elements be present in a sample under examination is not beyond the power of anyone possessed of an ordinary acquaintance with chemicals.

The substance is usually better examined in solution, and, when in the form of insoluble silver salts, can easily be made soluble by digesting with dilute sulphuric acid and a few fragments of zinc, the silver precipitating and leaving the zinc salts in solution. The iodide can be thrown down as subiodide of copper when all those salts are present; in presence of bromide, protochloride of palladium throws down iodide only, or, when chloride accompanies it, nitrate of protoxide of palladium. Bromine in presence of the other two is readily formed as follows:—Mix the fluid with a few drops of dilute sulphuric acid, then some starch paste, and afterwards with a little fuming nitric acid. The well-known iodine blue with starch is produced and must be destroyed by the gradual addition of chlorine water. When it has disappeared more chlorine water is to be added, the effect being to set free the bromine, which can be taken up by chloroform by shaking a little of it in the test-tube with the liquid. The chloroform will then show the characteristic colour. Chlorides are best detected by precipitating the salts with silver, and, after washing, treating with dilute ammonia, which, as our readers know, readily dissolves the chloride and also dissolves bromide, but only a trace of iodide. The filtrate has to be dried and fused with carbonate of soda, the result extracted with water and neutralised with sulphuric acid evaporated again, the residue fused with bichromate of potassium, and a little concentrated sulphuric acid added. A deep brownish-red gas (chloro-chromic acid) is evolved.

The above is an epitome of some of the readiest of the usual methods for testing for these compounds, and we now give, in as short a space as possible, two methods—lately-published modes—recommended as simple means of effecting the same end, one also estimating the relative amount present. The first we give is the subject of a communication to the *Chemical News*, under a well-known and respected name—Mr. F. Maxwell Lyte. It is founded on a familiar method of estimating the amount of these three halogens present in a mixture based on the property shown by Field to be possessed by one halogen silver salt, of being changed by treatment with a solution of an alkaline salt of another halogen. Thus, chloride of silver is completely changed by digestion with a solution of bromide of potassium, and bromide and chloride by iodide of potassium, a mutual exchange taking place. These reactions are a conspicuous example of the reversal of the "table of affinities." Mr. Maxwell Lyte writes:—

"The haloids having been precipitated together with silver, the precipitate is to be collected, dried, and weighed. It is now dissolved in about thirty or forty times its weight of water by the addition of the least possible quantity of cyanide of potassium. A quantity of pure bromide of potassium is now added, which need not be above the weight of the precipitate. The cyanide is now decomposed by the addition of an excess of dilute sulphuric acid. The precipitate in which any silver chloride has become, by this means, converted into silver bromide is now collected in a filter, dried, and weighed. It is once more dissolved in the least possible quantity of cyanide of potassium in the same quantity of water, and to this is now added one and a-quarter time the original weight of the precipitate of potassium iodide. The cyanide is now again decomposed by dilute sulphuric acid, and the precipitate once more collected in a filter, dried, and weighed. In the last precipitate all the silver is converted into iodide, excepting such as was iodide already. In the second all became bromide excepting such as was bromide or iodide already. From the weights thus obtained from the first, second, and third weighings the chlorine, bromine, and iodine can easily be calculated."

The other method we would call attention to is by Mr. Francis Jones, and is also found in the same journal. He states that, having compared the results obtained by his students when using this and other methods, they are far more successful with the new method:—

"Place a *small* quantity of the mixture to be tested in a good-sized test tube, and add a few pieces of manganese dioxide; then a little water. Add now *one* drop only of dilute sulphuric acid (one part acid to ten of water). A brown tinge indicates the presence of iodine. Boil the mixture and confirm the presence of iodine by the violet vapours in the upper part of the tube. Continue the boiling until these vapours cease to appear; then add another drop of sulphuric acid, and boil again until they cease. If necessary, repeat this addition of acid and boiling until violet vapours have entirely ceased. Now add about two cubic centimetres of the dilute acid, and boil again. Brown vapours indicate bromine. Continue the boiling until the vapours no longer smell of bromine; then add one cubic centimetre of dilute acid, and boil again. When the vapours no longer smell of bromine allow the residue to cool *completely;* add an equal bulk of *strong* sulphuric acid, and warm. A green gas bleaching a piece of moist red blotting-paper at the mouth of the tube indicates chlorine. Occasionally some bromine comes off in the addition of the strong acid; but, if so, it is soon got rid of, and is succeeded by the chlorine, which is chiefly evolved in warming the mixture. As, moreover, moist red blotting-paper is far more quickly acted on by chlorine than by bromine, there can be no difficulty in distinguishing between the two elements."

Two very useful methods of analysis—the latter within the power of any operator of average expertness to carry out—are here indicated, and we think they will be found as useful in practice as in theory. They show the futility of trusting to tabulated degrees of chemical affinity.

The Late Mr. J. H. Dallmeyer.—It is with sincere regret we have to announce the demise of one whose name has been long identified with the manufacture of optical instruments—photographic lenses, microscropes, &c. He was on a voyage to New Zealand for the benefit of his health, and died when within view of that coast. In our next issue we shall give a memoir of Mr. Dallmeyer. Meanwhile we may state that the business will be continued by Mr. Thos. R. Dallmeyer, son of the deceased gentleman.

We mentioned last week that the *Illustrated London News* had recently given a frontispiece engraved from a photograph. Now it is the *Graphic* which has adopted a similar course. The frontispiece of the volume for 1883, which was issued with the last number, entitled *Feeding the Pigeons, St. Mark's, Venice,* is from an instantaneous photograph by Mr. J. J. Acworth, who has recently contributed a series of articles to this Journal.

While on the subject of photography in its connection with our illustrated papers we may revert to a remark we made some little time ago, to the effect that photography might soon hope to find new applications in that direction. We were not at that time aware how soon, and to what an extent, photography would be so utilised; but, at the present time, at least two of our leading illustrated papers are using photography in the production of their illustrations. The *Pictorial World* has recently given a number of pictures which but for the scarcely noticeable words "ink-photo," in one corner we should have taken to be ordinary lithographs of the best class. They are, however, produced by Messrs. Sprague and Co's. photo-lithographic process, several examples of which have appeared in our own pages. Messrs. Sprague and Co. have also supplied type printing blocks to the *Illustrated London News* and for some time have regularly illustrated the *Architect.*

THE subject of Mr. H. J. Newton's mercuric developer, described in the *Photographic Times* of November, was brought before the last technical meeting of the Photographic Society of Great Britain. In the last issue of our New York contemporary Mr. Newton, afraid lest a blunder should arise in consequence of what he calls any foolish version of it being given, has carefully reproduced his directions, which we summarise thus:—Thirty grains of bichloride of mercury having been dissolved in four ounces of water, and ninety grains of iodide of potassium having been also dissolved in one ounce of water, the latter is then poured into the former. This mercuric solution is used in connection with a developer, on the precise composition of which Mr. Newton lays great stress—

Carbonate of soda (washing soda)	25 grains.
Sulphite of soda	4 ,,
Pyrogallic acid	2 ,,
Water	1 ounce.

The instructions for developing a very briefly-exposed plate is to bring out as much as possible with the developer for four or five minutes, and then add three drops of the mercuric iodide solution for every ounce of developer. This brings out details which could not otherwise appear. During the dull weather now prevailing it will be desirable that Mr. Newton's formula receive a fair trial.

BORACIC acid—which, as our readers are aware, has been recommended for use in several photographic processes—is a most troublesome material to pulverise. A method stated to be the best yet discovered is to grind it up in a Wedgwood mortar, keeping it moistened with ether all the time. This may possibly answer; but it must be a very unpleasant, not to say costly, method.

THE recent lantern exhibition of the South London Photographic Society was an undoubted success. The lanterns were manipulated by Mr. William Brooks as though he had been "to the manner born;" while the free and easy, jaunty, never-in-the-least-put-about style of Mr. F. Bridge, the Secretary, by whom the various pictures were explained, kept the large audience in excellent humour. The dissolving of one picture into another, the uniform steadiness of the light, the brightness of the eighteen-feet disc, and sharpness of the enlarged images were such as to reflect the highest credit upon all concerned. The large hall was crowded to excess, and the pictures exhibited numbered between two and three hundred.

OUR readers will remember the ingenious conception of a well-known *savant* to show the comparative slowness with which the sensation of touch is conveyed. He said if it were possible for a child on the earth to put out his hand and touch the sun he would have grown old and grey before he became aware of the sensation. M. Paul Bert has recently presented a note to the *Académie des Sciences*, Paris, in which are described further experiments by M. Block to determine the rapidity of visual and other perceptions. Vision is the most rapid; hearing occupied $\frac{1}{75}$ of a second longer; while the sensation of touch required $\frac{1}{24}$ of a second longer for transmission than a visual perception.

ANYTHING more forcible than these facts to prove the superiority of photographic over personal observation of astronomical phenomena cannot be imagined. These ratios are, no doubt, averages, and every observer will have his own rate of perception, though, quite possibly, the relative speed of perception will not vary in individuals. In taking transit observations, for example, with one man to count seconds aloud, another with his eye at the telescope, and a third to note down the actual observer's calls, we see how the real moment of contact or what not—being governed by the perceptions of those persons before the time is written down—may possibly be subject to perceptible discrepancies in the hands of different observers. Indeed, in most observatories, the "personal equation," as it is termed—that is, the rate of perception, and its audible expression, of each assistant—is always ascertained, and the records he makes reduced in accordance with it. In photographic observation, however, with a chronometric arrangement, so contrived that the plate records its own time, no error can thus occur.

A SUGGESTION is made in the *Photographic Times*, namely, that the Stock Dealers' Association of America pass a resolution calling upon dry-plate manufacturers to test the sensitiveness of their plates, and mark upon the outside of each packet both the number of the emulsion and its sensitiveness, this latter point being determined by a recognised sensitometer, such as Warnerke's. The label on the emulsion would, therefore, be marked in somewhat the following way:—

Emulsion, No. 1103. *Warnerke*, 22.

To understand the above thoroughly it is necessary we should say that the Stock Dealers' Association appear to command the situation in America.

WE should like to hear the opinions of some who hold that vitrified enamels are subject, in some instances at least, to fading. Although it is not easy to discover in what way they fade, provided perfect vitrification of the enamel surface has occurred, yet, from opinions we have heard expressed, it is probable that fading of some sort has really in some instances taken place. Seeing that burnt-in enamels are looked upon as the highest representatives of photographic permanence, it would be well to have the matter set at rest.

M. HENRI BECQUEREL continues his investigations upon the infra-red portion of the spectrum, and records some most interesting results. We need not explain that this part of the spectrum is entirely invisible to the naked eye; by means of the methods he adopts, M. Becquerel shows that there exists in this invisible region bright line spectra—also, of course, invisible—just as are seen in the visible spectrum the radiations from hot vapours. For example: incandescent sodium vapour shows two well-marked lines (wave-lengths 819 and 1098) corresponding to two bright lines hitherto unknown.

THE method adopted by M. Becquerel is as interesting as it is novel. Hitherto there have been three modes of investigating the part of the solar spectrum under consideration—the first involving the use of a thermopile and a rock-salt prism; the second, Captain Abney's photographic method; the third, Professor Langley's method, with his bolometer and a diffraction grating. This new mode, however, differs from any, and is based upon the discovery that the rays of the ultra-red spectrum have the effect of extinguishing the glow of a phosphorescent body previously exposed to the opposite—the ultra-violet—end of the spectrum. By this means water, for example, gives three well-marked absorption bands with wave lengths 930, 1,080, and 1,230 respectively. Some idea of the degree to which the spectrum is extended beyond the limits once assigned to it may be formed when we learn that this phosphorescent process enables a region from wave length 760 to 1,300 to be examined—that is, an extent greater than the whole of the visible and ultra-violet rays combined.

IT is a very good thing to have a knowledge of the mode of preparation of the various chemicals of the dark room, and any periodical that assists in bringing such knowledge before its readers is doing useful work. We were amused, however, to read, as we lately did in a monthly trade journal, that hydrobromic acid is recommended to be made as follows—"100 grammes potass. bromid. are mixed with 280 grammes of phosphoric acid of a specific gravity of 1304. This mixture is put into a half-litre glass flask. A molten potash metaphosphate forms, and chlorine is given off. Pure hydrobromic acid fumes at last pass over, which should be received in distilled water." While wondering where the chlorine came from we could not help also wondering what possible end is subserved by such paragraphs.

M. G. LEMOINE has contributed to the *Académie des Sciences* of Paris a note on the employment of ferric oxalate (or, rather, of a mixture of ferric chloride and oxalic acid) for the purpose of light-measuring. We shall probably, at an early date, give an extended account of M. Lemoine's results.

In the course of conversation, a few days ago, on the subject of coating plates by mechanical means, we were reminded of a rough appliance for this purpose which we constructed experimentally some three years or more ago, and which, if elaborated, would probably prove useful in the hands, at any rate, of amateurs and small producers of plates. It is based upon the same principle as the well-known stylographic pen, and consists of a wedge or other shaped vessel of the same length as the plate to be coated, having a slit or opening along the whole length of its lower side. This slit is closed by means of a strip or wedge of glass or other material dropping by its own weight into the opening, in the same manner as the needle in the "Mackinnon" form of stylographic pen. If the trough or vessel be filled with emulsion this movable slip or stopper prevents its egress until the slip is pressed in contact with a glass plate, when it is raised and permits the emulsion to escape. By slowly passing the arrangement over the surface of a plate it is obvious that a coating of emulsion may be applied varying in thickness with the rapidity of the motion.

UNSUSPECTED CAUSES OF STAINING IN GELATINE PLATES.

In the days of wet-plate photography with collodion films we seldom or ever heard of any staining of the film after varnishing, but with gelatine films it is not uncommon; indeed, as a rule, I think the complaint is more or less general. There is one cause of staining or spotting of negatives, but I cannot call it an "unsuspected" cause. Many photographers—amateurs especially—like to try a print from their negatives before varnishing, so that if they are not just right as regards density, they can be altered before varnishing. This is all very well, so far as it goes; but, if silver paper be applied to the negative before varnishing, sooner or later spots will show themselves.

If I require to see a print from a negative before varnishing, I always like to make sure that no evil result will accrue from it; so, to guard against the spots through this cause, which are so well known, after taking the print I give the film a slight wash of a weak cyanide solution. This will remove any particles of free nitrate of silver that may have attached themselves to the film from the paper. The best way I find to apply this, so as not to injure the negative, is to first soak the negative well in water—say for about a quarter of an hour—and then apply the cyanide solution with a flat camel's-hair brush about half-an-inch in width.

I find cyanide need not be more than about three grains to the ounce of water, but not more than five grains at the outside. Fully charge the brush with the solution, and pass it over the film lightly, re-charging it occasionally. Care must be taken that the cyanide is applied to the whole of the film. About one minute will be found quite sufficient, as it is only required to act on the surface of the film and not in it. After the negative has been thus treated and well washed, I have never found any staining from the cause named.

An unsuspected cause of staining is when a negative has been known to have been well washed and varnished and then placed aside for a few weeks, and not been printed from, on looking at it to find it all spots and stains. My attention was called to this kind of staining some six months since. As it seemed to me very peculiar I examined the plate well, and at last I suspected the varnish. I remembered that I had a sample of a similar varnish at home, which I had had by me for years, and was of a very sticky nature. I well washed a useless negative thoroughly, varnished it, and laid it aside on a shelf. After a time the spots and stains began to make their appearance in a similar manner to that in the one before mentioned. The cause with me was not far to seek; the varnish was at fault undoubtedly. The varnish was very strong in smell, containing gum benzoin and Venice turpentine. Now my experience with the latter article is that it darkens all silver compounds with which it comes in contact, and is very unsuitable in a photographic varnish. I see by a very old book on photography in my possession that such a varnish is mentioned.

For nearly twenty years I have always made my own varnish, and have never had any trouble with it. At one time I used to employ several of the gum resins; I now only use the best shellac dissolved in alcohol. I find it exceedingly hard, and it does not stick in the hottest sun. To temper it a little I add a small quantity of castor oil, which I find answers all purposes.

Why varnish-makers use such a combination of gums I cannot imagine. My idea of the gums for varnish-making is that the less odour a gum possesses in its solid dry state the more durable will be the varnish; for I consider that a gum which throws off any smell is throwing off solid particles, and a varnish made from such a gum causes it to crack. The lacs, I find, are almost entirely without odour. Sandarac smells stronger, and gum benzoin stronger still, and that is why I reject these gums and give preference to the lacs. There are several varnishes in the market that I should be very sorry to use on a negative of any value.

Another cause of staining I attribute to intensification with iron, and that is why I use pyrogallic acid in place of sulphate of iron. I saw some negatives the other day that were intensified with iron which had become stained more or less, while others that were done at the same time with pyro. had not stained.

All the gelatine plates I use I make myself, and I never employ more gelatine than I am obliged to do, as I consider the less gelatine used the more easy is the washing. I do not employ more than about half the quantity that is generally prescribed.

There is also another cause to which I think sufficient attention is not paid, and that is in the fixing. A great many, as soon as the unaltered bromide and iodide have apparently disappeared from the film, take the plate at once out of the hypo. and wash it. I have found, from experience, that the plates should be left five or ten minutes at least after the film appears clear; for, if it have a thick end to it, it takes some considerable time to free it from the bromide and iodide. If these have not been entirely removed and silver intensification be employed afterwards, a dark yellow stain will appear which nothing can remove. I have seen this on several occasions. By some it is said to be a hypo. stain. If silver intensification has not been employed, and the negative has *not* been properly fixed, discolouration is sure to occur sooner or later, no matter how much the plate has been washed; and, therefore, I think too much attention cannot be given to fixing or clearing a negative, which is very often slurred over. WM. BROOKS.

GELATINO-CHLORIDE FOR TRANSPARENCIES.

I HAVE long sought for a method of producing transparencies by contact from certain negatives, and I desired to find a method by which I could produce transparencies at once suitable for household decoration and for the reproduction of negatives in case any accident should happen to my originals. In the current ALMANAC I briefly stated the importance of such a step being taken in the case of perfect negatives for insurance against total loss by accident, and in the case of negatives requiring intensification or reduction to prevent loss through the mistakes so frequently made in these operations. That my remark in the ALMANAC is worthy of notice I am persuaded to believe from the facts that the Editors of this Journal have chosen my words as the text for a valuable and carefully-written article, and that disasters to valuable negatives are frequently occurring and always possible. A broken negative has, before now, in very deft hands, been patched up so as to give passable prints—at least so I read; but if a negative be smashed to "smithereens," as I have seen them, no mortal can replace, even if he can collect, the fragments.

And who can be certain of succeeding in the intensification of a gelatine negative? I, for one, confess my dislike, and even dread, of the operation, which, in my hands, has always been precarious—often disastrous—though I have given great care and study to the subject, and tried every published process that had a germ of rationality in it. The same remarks may apply—perhaps in a slightly modified degree—to reduction. Negatives over-dense can be reduced with tolerable certainty; but not seldom the reduction is overdone, or the gelatine incurably damaged, by the reducing agent. If a valuable negative can be rapidly, easily, and certainly reproduced as soon as dry, I submit that a great advantage has been gained. If, however, we produce not only a duplicate, but a superior negative, and if, further, our intermediate positive is a thing of unusual beauty, a valuable decoration, and a profitable commercial commodity, then I maintain that not only is our slight trouble amply repaid, but our ability of executing orders which might otherwise be lost is ensured.

Now I know that most professional photographers will agree with me, so far, as to the desirability of making contact positives of their negatives; but they will demur to the trouble, the expense, the time, and the extra accomodation required for carrying out what I urge. Well, I admit at once that more room will be necessary for the storage of negatives and positives, because in this, as in other matters, I like to look at all sides of the question. But how about my friend of the Exhibition who had a large and, to him, extremely valuable negative broken after the production of seventeen prints, the subject being a public ceremony which could not be re-enacted for his benefit, and the negative of which was a brilliant success that might have made his name renowned and left his pocket bursting? I guess he would not grudge the space required for a good positive on gelatino-chloride. And consider, also, that any valuable negative is liable at any time to be broken—all the more so because valuable. Everyone knows that when a large number of prints is wanted of a certain negative such negative is reproduced over and over again, thus saving time and avoiding superfluous wear and tear of the original negative. With gelatino-chloride plates, as I propose to recommend them, the time, trouble, and expense are as nothing compared with the advantages gained.

I have already said that the positives produced by contact printing with either portrait or landscape negatives are themselves things of beauty and eminently marketable commodities. No silver print can at all compare with either a transparent positive or a good positive on opal, whether the opal be matt or smooth. To-day I have produced in a couple of hours, and with one dose of developer four ounces in quantity, eight positives—six on opal and two on glass; and, though the batch of plates was new, I have not lost one operation. I was endeavouring also to produce a variety of tone, and in this I have succeeded, no two positives being alike in colour, yet all pleasing enough.

All my previous experience did not amount to eighteen trials, and of these trials were two batches of emulsion made by myself and differently treated, while the other experiments were made with plates prepared by the versatile and ingenious Mr. A. Cowan. Any person in possession of his senses would prefer these experimental positives of mine to my silver prints from the same negatives; indeed, I showed an opal to a person whom one of the negatives represents, and it was with difficulty I could resist the "annexation" of my opal property. Had it not been that I happen to hold the "suzerainty" of the person in question, my Transvaal — I mean my opal — would assuredly have been forfeited.

The positives on glass, too—backed with opal or ground glass or matt varnish, then the edges bound or the plate framed—make lovely objects to hang at a window or exhibit in a slanting frame on a table. If photographers would have the windows of their reception-rooms hung with such goods they would interest their clients and secure most profitable orders; for these positives have an *appearance* of great value and would command a high price, though the cost of production is but trifling. The ease with which these opals, especially, can be worked upon and beautified is a matter of great importance, whether the positive is to be sold or a new negative to be produced from it.

But I am writing so strongly it would almost appear that I have a commercial interest in some plates or some process. This, however, is not the case; all my interest is comprised in a thorough love for our art, in a firm conviction that we have in store a greater and nobler future than anyone yet imagines, and in a warm desire to point out to photographers what is really for their benefit, artistically and pecuniarily.

I have no doubt that almost any sort of emulsion in good order will serve to produce good or passable positives; but with emulsions anything like what we call "rapid" the difficulties are greatly enhanced. Given a slow emulsion, the trouble decreases very greatly; an artificial light may be used, and either pyro. or iron development will answer the desired purpose, so far as required for the reproduction of negatives. In this way I have successfully used various sorts of dry collodion and albumen plates, also Swan's slow gelatine plates; and I found some of Mr. Kennett's original gelatine plates, with excess of silver, I suppose, give capital results.

And here I must state what I consider the *desiderata* for positives to be used for reproduction of negatives, and for final prints of themselves. In some points the desired qualities tally with each other; in others, by slight modification, they can be made practically to agree. In both cases we must have fair density and clear shadows. The high lights must be clear glass, but there must be good gradation from this to the dark shadows, which for their part must be "firm," but not opaque. A positive without any half-tone, or a sudden jump from clear glass to dense darkness, is a "waster." I found that with (say) a bromo-iodide gelatine plate, when I got a good, brilliant positive for reproducing it, it was rather too dense to make a first-rate decorative article; nor, as a rule, was the colour suitable for a picture by itself. It was only occasionally, and always with much trouble, that I could tone a gelatine plate with bromide in it to a good colour, and even collodion positives were not to be depended on in this matter.

But at last I have found an emulsion of gelatine and silver chloride which, while possessing agreeable colour, is also eminently suited for the reproduction of negatives; and a positive on gelatino-chloride emulsion can be first used to reproduce the original negative and then used as a decoration. Or it can be put aside, or even sold as a work of art, and yet serve as a matrix for the reproduction of negatives at any time when the artist may get hold of it, as in the case of the original negative getting broken. I say I have found such a process; but I do not mean to infer that I discovered or invented it myself. I got my ideas from the writings of Mr. Cowan, who gave his process to the public with most commendable liberality. In the exposure and development of these plates, almost any variation of colour may be produced; and, further, if the finished transparency be not of the desired colour, it can with perfect ease be changed, if not to any colour, at least to several most pleasing tints.

On getting a copy of Mr. Cowan's original formula and directions for making gelatino-chloride emulsion, I, as usual with new processes, proceeded to make a batch of emulsion for myself. I do not know whether it is worth while to fill these columns with what can be found elsewhere; but, in a very few words, I shall describe my operations. I took 320 grains of gelatine (Nelson No. 1 and Heinrich equal parts), soaked in six ounces of water for an hour, added 146 grains of ammonium chloride, raised to about 110° Fahr. I also took 320 grains of silver and two ounces of water at about 110°, dissolved and added slowly, with brisk agitation, to the chloride gelatine; then I raised the emulsion to 125°, and turning off my gas left the whole affair covered with flannel for ten minutes, after which I poured out the emulsion to set.

This was on October 28th. On November 2nd, on my return from a short absence, I washed, filtered, and coated plates with the emulsion. When dry they gave positives by contact as good as I could wish, but the emulsion was too slow for copying in the camera. Then I took part of the emulsion which had not been washed, and boiled it for fifteen minutes; afterwards washed it, filtered it, and coated some quarter-plates with it, and tried to copy negatives in the camera for lantern slides. I found this a failure, as fog was present in sufficient force to spoil a lantern transparency, if not any positive. I tried various developers—ferrous oxalate, ferrous citrate, &c.—but none of them would work for my purpose.

I may as well say at once that I do not recommend these chloro-gelatine plates for camera work. If the emulsion be not boiled it is too slow; if it be boiled there is always the fear of fog, to which, in my opinion, a boiled chloride emulsion is at all times liable. To make certain I repeated the experiment twice, boiling the emulsion five and ten minutes respectively, and the result was the same—fog; not violent, but enough to impair a lantern slide. I am told that a gentleman has used the unboiled emulsion plates for slides, exposing only five minutes in the camera; but I am not told what lens or what stop he used, nor do I know if his slides are anything like sharp in focus.

After I had prepared my emulsion as above, I noticed that Mr. Cowan's plates were to be had from the maker. As I have resolved not in future to prepare emulsion except for special purposes, or for the sake of experiment or keeping my hand in, I at once requested Mr. Cowan to send me a batch of plates—a few to be boiled emulsion. I see no reason why I should not say that I was charmed with these plates from the very first. As prepared by Mr. Cowan himself the plates were excellent. I wish all processes came up as thoroughly to what is claimed for them as this one does. I am told that the preparation of these plates has passed into the hands of Messrs. Marion and Co., and I have no reason to doubt that the plates will continue to bear the good character I have to give them. Tones ranging from cold, slatey grey to bright scarlet or carmine can be produced almost at will, and the exposure is of so elastic a nature that one can hardly go far wrong in the matter. Upon the duration of exposure, or upon the consequent modification of development, depends chiefly the tone of the finished transparency.

My practice is to expose the plate in contact with my negative—unvarnished for choice, but quite dry—to the worst daylight I can find for from one to six minutes, according to my negative and the tone I want. The redder the tone required the longer the exposure. That is the first grand principle. Mr. Cowan gave me quite a long list of alkaline substances with which I might develope—each of them in a certain proportion, and each counteracted by a proportionate amount of citric acid; and here comes in the second grand principle:—The greater the excess of acid in the developer the warmer the tone.

I tried three of Mr. Cowan's developers (those given in his printed instructions), and I found the last—that with the largest excess of acid, coupled with the longest exposure and restrained by a dose of common salt—to be the best. My plates requiring about four ounces of developer, I use the following:—

Citric acid	540 grains.
Carbonate of ammonia (fresh)	180 „
Water	3 ounces.

I heat the acid and water, and add the ammonia; this makes a "fizz," but does no serious damage to anyone. Into these four ounces I put from ten to thirty drops of a ten-per-cent. solution of pure sodium chloride, which, as I said, acts as a restrainer. To this add iron protosulphate 140 grains, water one ounce, and, if required, sulphuric acid one drop.

Development generally takes some minutes to begin; but when it does start you must "stand by to belay," as once on the move it works pretty rapidly. To tell the truth, my first plates took so long to start development that I put them into the sink and gave a much longer exposure to another plate. Meantime my rejected plate had started to develope, and I only noticed it by accident in the sink. Third grand principle—more salt, slower development.

Sometimes the image comes at first a grand carmine colour, and as development proceeds loses that tone. In such a case more exposure and shorter development is required. Fix in hypo.; no alum or acid required. If anyone attending to the printed instructions alone can make anything but fine positives from decent negatives, all I say is I don't "twig" how he does it. The fixed and well-washed positive can be toned with perfect ease, if the colour do not satisfy, to several beautiful tones with gold, or borax, or platinum. Gold works well, as I can testify. If transparencies of this kind are made on opal the development must not be carried too far. If the opal be matt, the surface is about as perfect for retouching with pencil or brush as anything I ever saw. Portraits and landscapes are also valuable when printed in this style, and, as I maintain, look better on glass than in any other shape I know.

To produce a duplicate negative from such a positive, nothing is required but to repeat the operation. This time, however, I use a slow bromo-iodide plate, printing by artificial light through ground glass or opal, and develope with pyro. But another chloride plate may be used without doubt. People are always raving about clear glass shadows in a negative; well, I don't like *any* clear glass in negatives, unless my shadow is in nature not only black, but *dead* black.

I omitted to say before that the developer I have given works quite well for six or eight plates, but does not keep for many hours. The two solutions composing it, however, will probably keep separately for a long time. ANDREW PRINGLE.

POLYCHROMATIC NEGATIVES AND DEVELOPING-ROOM ILLUMINATION.

MR. DEBENHAM's announcement that ruby light is not the best for the development of gelatino-bromide plates raises the desire of those in foreign lands to examine the matter; but no verbal or written description can exactly describe the particular shades of colour he used, nor if I had a specimen of the glass here would it be of use, because I have resolved to discard glass-faced lamps when travelling. Such lamps are heavy if of serviceable size, and glass breaks. Naked yellow lights worked at from a safe distance, or pasteboard candle-screens with paper windows are preferable. The objection to the latter is that paper tears, and that no enterprising manufacturer has yet introduced coloured oil silk into photography, for that would be a great boon.*

However, I hit upon the following simple plan of producing Mr. Debenham's results, and anyone far from London can do the same without previously knowing the exact colours used by him.

I took a plate of bare glass, quarter-plate size, and bought at a shop nine sheets of tissue paper, of various red, yellow, and green colours. I fastened two slips of each of them on the glass—one set of nine slips longitudinally and the other set of nine transversely. The majority of the nine colours were green and yellow, the absorption of actinic rays by the red being so well known already. A broad margin was left at the edges, because the strips were there fixed to the glass by gum. The gum spread a little while wet, under the necessary pressure of the fixing, but, because of the margin, it could not spread to where the strips crossed each other, and so interfere with the results, paper rendered more transparent by gum not being in general use for photographic lanterns.

Thus, by nine slips crossing the other nine slips at nine different places, I had no fewer than eighty-one squares of two thicknesses of coloured paper on but a single quarter-plate, so it was unlikely that some of these would not give results of interest. No doubt many will repeat this experiment, it gives such a large choice of coloured screens from which to select; but I recommend them to take a half-plate, with at least twenty colours in each direction, as when making a polychromatic negative it is as well that it should have a large range of colours, since that will require but a few minutes' extra work to prepare, and the negative when made will be permanently useful. The ends of the strips I turned round about one-sixth of an inch on the other side of the glass, and gummed them down there also, that they might hold on well.

I then exposed the polychromatic negative over one sensitive gelatino-bromide plate for seven minutes to the light of a common composite candle, and another similar plate to the same light for twelve minutes; the measured distance from the flame in each case was twelve inches. Both plates were developed at once in the same dish with the sulphite of soda pyrogallic developer, and both were fixed at one time in the same bath of hyposulphite of soda. The result was the discovery that many of the squares of superimposed papers had stopped the action of light well, and on searching among the coloured squares which had behaved well for one, which also gave plenty of luminosity to the eye, I judged the best to have been formed by one of the light yellows with one of the light greens—the result thus agreeing with those of Mr. Debenham, although some other tints answered nearly as well.

Knowing the eye to be useless as a judge of the pure elements of colour, I had a suspicion that the greyish-green light passing through the paper might, nevertheless, contain much of our old friend the photographically-useful ruby luminosity in disguise, and proving by its presence that the fairly-well-established first principles of science were really not upset by the apparent results of one experiment. Accordingly, I brought the spectroscope to bear upon the light of a candle passed through the two papers, when I discovered that, practically speaking, the transmitted light was a mixture of ruby and green, with a small preponderance of the latter, and that the blues, violets, and yellows were cut off, with the exception of a barely-perceptible trace of yellow. The red and orange papers, of which but one each had been used, answered well photographically and badly visually, as we all know; and the fact was apparent that the superposition of one of these colours upon itself gave little additional chemical protection, whilst vastly-diminishing the luminosity to vision by increasing the opacity of the screen. The little advantage gained chemically was probably due to the second sheet of orange paper cutting off rays which the grain and imperfections in the first sheet had allowed to pass; for tissue or any other ordinary paper is an unscientific and improper material to use in photographic lanterns, and its defects are made up by extra strain upon the eyesight of the operator. At those intermediate places where only a single sheet of coloured paper screened the sensitive plate the grain of the paper printed itself upon the film, showing the coarse nature of paper when used as a filter for light.

Mr. Debenham's experiments does not prove that his light was more non-actinic than ruby, although the latter allowed a print to be taken through it quicker than through the former. In the one case he had a screen of two colours, the one cutting off actinic rays to which the other was transparent, whereas he gave ruby light but the benefit of two screens of one colour, so that the chemical rays passed by the one would for the most part necessarily pass through the other also. Had he used two kinds of red, or ruby glass superimposed on orange, it is probable that the actinic rays would be more powerfully cut off than by his greyish-green, although the latter is more valuable for ordinary practical purposes. There is thus no evidence that his experiment necessitates a reconsideration of what at present is accepted as the first principles of spectroscopy as applied to photography.

In order to discover whether with light of a different space-penetrating power the same results would be obtained with the polychromatic negative, and another two colours prove superior with another source of light, I took the coloured negative today to Mr. K. Ulmi, a Lucerne photographer. He developes by means of a paraffine flame shining through ruby glass, and one of his plates, made at Twann, was exposed for eight minutes under the coloured negative at a measured distance of thirty centimètres from a bright paraffine flame about the size of a common candle, and with a tin reflector behind it. His was a rapid plate, made for portraiture. The results were the same as with my, perhaps, slower plates. His plates were developed with ferrous oxalate.

These tests were very severe as to the safety of the light, for nobody in ordinary operating holds his dry, undeveloped plates at right angles to a candle or paraffine flame for eight or twelve minutes. Their position is usually horizontal in relation to light, which diminishes the power of the latter immensely, and in less than a minute development has begun. Then, again, he does not necessarily work at but twelve inches from the light; at a distance of twenty-four inches its chemical power is diminished fourfold. The law that the intensity of light diminishes inversely with the square of the distance is a most valuable practical guide when developing by means of coloured lanterns. It is well, and quite as easy, not to let the plate be too close to the lantern in taking it from the slide and placing it in the dish; but, when once the developer is over it, it may be brought close to a fairly good lantern with impunity. A good plan is not to bring it very close to the lamp till the image just begins to appear.

* Our correspondent is misinformed on this point, as coloured oil silk for dark-room purposes—both orange and ruby—has been in the market for many years, and is quoted in at least one advertisement in our ALMANAC.

A chief reason why light will not act perceptibly on the film, even while the pyrogallic acid is colourless and when the lantern is faulty in the power of cutting off actinic rays, is that all polished transparent surfaces have a "limiting angle," at which angle all light falling on the surface is totally reflected, and none of it can pass through the transparent medium. Clear water or any similar medium thus rejects altogether a portion of the light falling upon it, and much of the remainder is reflected upwards when it falls upon the plate at the various angles of its emission from a developing lantern. Glass has its fixed limiting angle, water another, and probably saline solutions a different angle still. Here, away from books of reference, I cannot state the angles, but hope Mr. Debenham or someone else will look them up and publish them; for it is evident that the centre of the lantern glass should be at such an elevation above the centre of the developing dish that the line of light between the two shall fall upon the liquid at its limiting angle. Instead of the lantern glass being placed with its greatest length perpendicular to the plane of the horizon, its direction should be horizontal, that more of the light may fall on the developing dish near the limiting angle. It is also a mistake to make the other three sides of a square lantern of metal; they should all be of non-actinic glass. The light from the other three sides does not fall direct upon the developing dish, but has to reach the sides of the room, in which any feeble actinic rays are more especially absorbed by the surface of the walls, and the operator may as well have the advantage of all this well-filtered light in his room. An operating-room in which daylight is filtered through coloured glass is more unscientific than one in which light from a screened flame is used; in the former case the conditions are constantly varying, and more dangerous to good results.

There are conditions under which ground glass will illuminate a room more than plain glass; and one is where the window is so near to the large blank wall of a neighbouring house that most of the light from the sky falls on the glass at the limiting angle, as it is thus thrown off outside the room. If the exterior surface of the glass so placed be ground, much of this light is caught at other angles by the infinite multitude of little hills and valleys and is deflected into the apartment.

The colour of the ferrous-oxalate developer is a great protection to a sensitive plate beneath it from the action of light. Pyrogallic acid has not this advantage in the first stage of the development. Some harmless and cheap vegetable ruby colouring matter added to it might be an improvement.

The days of miserable working in gloomily-dark rooms with gelatine plates are nearly over, thanks to the initiatory step taken by Mr. Debenham. In the early days of gelatine emulsion the plates were not so good as now, and the operators fogged them more by over-development, over-exposure, and too much ammonia. The blame must often have been laid on the unfortunate light, and the photographer afterwards punished himself by working more and more in the darkness of Eblis. In some cases no doubt the light was to blame from want of care in testing the transparent screen by trying to what extent it could be printed through, and because of using two thicknesses of the same glass, instead of varying the colour in the second sheet, that the latter might cut off the rays to which the first one was permeable. This error is common now, and rendered Mr. Debenham's comparative experiment an unfair and inconclusive one. Very likely the best red colour obtainable will still be the best for abnormally-sensitive plates.

The yellower or redder and the more steady the primary source of light in the developing-room the better. If a gas flame be used an argand burner should be chosen, because when the central air-hole of the burner is plugged at the bottom the flame is made longer and yellower. In the future more than ever should the Irish-like expression, "the light of the dark room," be abolished.

Since the previous portion of this article was written, I have read the account of the experiments of Mr. Herbert S. Starnes, which is another step in the improvement of operating-room illumination. It was probably an error to employ any white paint in his lamp as a substratum. What was wanted was that the blue rays should be absorbed by the wood and paint of the walls of the box, and none reflected. An orange or green, rough, unpolished surface might have been more to the purpose. His plan does not amount to much more than the method of developing by the light of an ordinary candle, with an opaque screen between the candle flame and the plate, with the latter at a safe distance. But it is a little superior in that more of the blue rays are absorbed by the walls of the box than by the majority of the colours used on the walls of rooms.

Mr. Debenham will be pleased to hear that his method is already adopted in Lucerne by Mr. Ulmi, who is greatly pleased with it. The one sheet of thin tissue paper is of a canary-yellow colour, and the green is a very bright pea green, inclining to yellow. Some of the darker greens I tried answered no better, but quite as well chemically though inferior visually. On examining the accepted papers separately through the spectroscope by daylight I found they each transmitted a little blue, but when superimposed cut it off, I suppose because imperfections caused by the coarse grain of the one paper were largely neutralised by the other, and because red and green rays have more power of penetration through coarse media than blue rays. This is why street gas-lights at a distance look redder and yellower in a London fog.

Those who wish to try the new light without the trouble of experimenting, will probably be quite safe if they buy the most brilliant green tissue-paper and the most brilliant canary-yellow tissue-paper they can find in a shop—not the feeblest or the darkest of the colours, but the brightest. The feeblest let more actinic rays through; the darkest shut out light by opacity, which light is wanted for the benefit of the eyesight. I wish to withdraw the statement in my last article to the effect that the new light was probably change of colour without change of intensity. There is a great increase of intensity, and Mr. Debenham has conferred a great boon upon the whole photographic world.

W. H. Harrison.

Lucerne, Switzerland, December 28, 1883.

"POLICE PRISONERS' PHOTOGRAPHS."

A glance at a collection of criminals' photographs, so largely used by the detective police, does not increase one's admiration for mankind. Most of the portraits seen in their albums have certainly been taken under the most dismal circumstances. The felon brought to bay is not seen in his happiest mood, and it is beyond ordinary human nature to look one's best with the almost dead certainty of a period of prison discipline in the immediate future.

Scanning the prints it is the simplest thing in the world to pass over an apparently harmless, uncharacteristic face, and hazard a wonder at its being in such bad company. The chances are that the original was one of the vilest of the lot, for there are those who can "smile and smile and be a villain," and it goes hard with the innocent prisoner's photograph; no matter what expression is portrayed, the surroundings condemn him and brand him as a "bad 'un."

Those fairly nurtured in crime and abandoned to the lowest strata have a physiognomy which needs no Lavater to distinguish. "Assume a virtue if you have it not," says Shakespere; but it will not do much good here, for in the unemotionable photograph the brute character shows clear. The beetle-browed ruffians are, if possible, rendered more than naturally hideous. Being mostly taken under a top light, with no attempt at modulating its direct vigour, the shadows are wofully abrupt. The lines and furrows of dissipation, scars, and broken noses are made even more disfiguring, and, further, the consciousness of being trapped and compelled to submit does not tend to mend matters; thus we have the criminal bully perhaps at his worst.

I have before me two prints showing the baffled rage of two low-browed scoundrels while four constables are energetically holding them down. In the one a great bar of wood is forced under the chin; it takes two men to manage it. This effects two objects—raising the head and nearly throttling the "subject." The hair of the head is firmly grasped by another, no doubt to keep him steady; a punch in the stomach by the fourth completes the picture. He has been posed with a vengeance! "He won't object the next time," said the burliest constable, as he wiped the perspiration from his face. In the other picture a bunch of keys jagged into the throat is substituted for the bar of wood, and seems as effectual.

These portraits were taken by the old wet process, when rapid exposure was not the rule. Matters are somewhat improved now, for in a few cases they are taken unawares. The album contains some striking evidence of this—one, for instance, with an officer's hand on the prisoner's shoulder in the act of giving friendly advice. This is, undoubtedly, the pleasantest way, but is not always practicable. Generally speaking, the taking of a prisoner's portrait is very commonplace. He is brought out of his cell, placed on a chair which has been previously focussed, sits down looking a little bewildered, a rapid exposure is made, and the untried unfortunate is hurried off little the wiser. But, be on your guard, constables and photographer! In an instant the demon of destructiveness rouses the sitter, and in a moment the apparatus is smashed with a display of astonishing energy and vindictiveness, recalling to mind the nigger in the "Octoroon" who tomahawked the camera with bloodthirsty revenge.

In the album is the portrait of a "card-sharper," who smilingly sat down, apparently delighted with getting his portrait taken; but just at the critical moment he jumped up and gave a vicious kick at the camera, making a wreck in no time. If ever a man got punished I can in confidence say he did, for the burly constables were at him with gusto, and by the time another camera and lens were procured he was a sadder *and* a wiser man. The best policy is here, as elsewhere, to submit to the inevitable. The police department, I may mention, made good the photographer's outfit.

The women criminals are the worst to manage when once they make up their minds to be troublesome, and I believe they are not much meddled with if they show many qualms. A good lady on one occasion bounced up from the posing chair with great vigour, and with a preliminary spit on the hands, looking all over like fighting trim, she said, "I was just going to smooth my hair," when she was roughly collared by the constable and thrown down again.

One lesson to be learned is to use, for preference, a long focussed lens, and then the photographer is not too near his sitter. Perhaps in some cases a brick wall between the parties is preferable. A very good plan practised at one station is in having two raised platforms—one for the camera and the other for the model; and, with a wide, empty space between, a sudden kick is here just wasted energy.

As there is no law to compel untried prisoners to sit for their portraits, it is scarcely to be expected that operations will always proceed in quietness. It is different in the gaol in which the convicted prisoners are placed. There everything is done by regulation. Those who have to be photographed go through the routine as a matter of course. There are, comparatively, very few untried prisoners who come under the camera's eye, and these few are special cases where copies are wanted in a hurry. In some instances as large a quantity of prints as can be done in time for the night's post or other mode of distribution is required. In pressing cases the detectives accept, in their urgency, rough, untoned silver prints. If the likeness be traceable it answers their purpose. I have no doubt that the gelatino-bromide paper will, if it is not already the case, be largely employed for this purpose. Its extreme sensitiveness (an exposure of one second or so to gas or other light) enables scores to be printed in an astonishingly-short time. A large batch can be developed at once, and finished and despatched to particular stations for information. For this, what are called "route forms" are used. The portrait is pasted on a printed sheet, and a written description annexed of name and *aliases*, place of abode, age, height, marks, occupation, charge, &c., and in some forms even their religion have to be filled in. These forms are forwarded from one centre to another, and carefully examined and noted. If recognised, particulars are communicated. In some energetic offices these "route" photographs are all re-copied and added to the album, there to be studied and referred to at any moment.

A great number of portraits, too, is in circulation of suspects not captured. From whence the detectives obtain these photographs is not easily explained; but the fact remains that the counterfeit resemblance of the forger, the embezzler, or other person "wanted" is in the hands of the police, and copies made.

Local photographers are often applied to for a *carte* of an unfortunate customer, and it is questionable whether they should give it or not. That they do often stretch a point and favour the detective there is no doubt; but, on the face of it, it seems a great breach of faith on the part of the photographer against his customer. Certainly, in a law-abiding, commercial nation it is every honest tradesman's interest to strengthen the hands of justice, and aid in the detection of crime; but in the case of the photographer he may be the cause of an irremediable injury. To have one's *carte* hawked about by a detective is to a sensitive man a punishment in itself, and with the doubt of guilt or innocence hanging over him is unfair to himself and degrading to his friends. It is no part of the photographic profession to place their private customers' negatives at the service of the police without the permission of the sitter. I should say, even where the case is as clear as noonday, the photographer has no business to betray his client.

The following is a case in point:—The assistant in a photographic studio, whose duty was to copy the "route" portraits for the police, happened to recognise in one of them the face of a regular customer. He compared the photograph, and there was not the slightest doubt. The person was "wanted" by the police for absconding with silver plate, &c., from his late employer. The address of the man—he was valet to a gentleman in the neighbourhood—was known to the photographer; yet he did not feel it incumbent on him to divulge the matter. The man might be a thief, or he might not. The photographer had found him honest in his business relations with him, and he gave him the benefit of the doubt.

Thomas Maitland Laws.

DIFFERENT DEVELOPERS.—EXPERIMENTS WITH A POTASH DEVELOPER.

The question as to what developer one should work with is still undecided. While in England (the fatherland of the emulsion process) alkaline development is used by an overwhelming majority, in France and, lately also, in Germany the ferrous oxalate developer is coming to the front. The circumstance that in England tourist photography plays a much greater part than on the continent may greatly contribute to this result. At anyrate, it cannot be denied that the question as to which developer is best suited for use on a journey is of great importance when one has to make a choice of a method of development. One must insist upon the same process being used always in the studio that is used outside it, and one can only learn to master his process thoroughly when he can employ it independently of time and place. From this point of view the following experiments were made:—

The ferrous oxalate developer offers the great advantage of being easy and convenient to handle, and furnishes plates which, when looked through, have quite the character of wet ones. It is, therefore, unusually well suited for use in the studio, especially since the price of potassic oxalate has become so low. Yet weighty considerations are opposed to its employment upon journeys or in warm climates. It is necessary to prepare saturated solutions of salts which do not dissolve very rapidly. These solutions must, especially where no distilled water is to be obtained to add to them, be filtered even when the chemicals are pure and fresh—a particularly wearisome business in the case of potassic oxalate—as rinsing water rich in calcium may not be used, while, of course, such a water is quite unfit for adding to the developer itself. The quantity of chemicals that have to be taken with one on the journey and the extent of the stock solutions are very considerable; and, finally, if the temperature be high and the plates are not prepared with very hard gelatine, the film dissolves in the baths. However great, therefore, the advantages of the ferrous oxalate developer are, such strong objections to its use occur in many cases that it cannot be regarded as a normal developer which may always be used.

The pyrogallic acid developer with ammonia takes up to a certain extent an opposite position. It is more difficult to manipulate than the ferrous oxalate developer, and plates developed with it have not when looked through the character of wet plates, if sulphite of sodium (which is such an advantageous addition) be not added.

Further: there is the still greater drawback that both the stock ammonia and the normal solution of the same as employed are continually changing, by long use, their specific gravity, and therewith their efficacy, and also that the strong fumes of ammonia evolved by the developer may become very annoying in the confined tent; but to these defects some unusual advantages are opposed. With sodium sulphite the developer furnishes plates which are in nothing behind those developed with ferrous oxalate, and which have thoroughly the character of wet plates; indeed, the alkaline developer allows, without any trouble, of modifications which can only be made upon the ferrous oxalate developer with difficulty and with the expenditure of time.

The chemicals required for the preparation of a normal solution occupy comparatively little room, are easily carried about, dissolve quickly, and, if salicylic acid be used with the pyrogallol, require no distilled water; but any water fit for drinking may be used for working with it as well as for rinsing the plates. Lastly: the film is so well tanned by the alkaline developer that the plates can be developed at a much higher temperature both of air and water (the latter may be used at 28° to 30°) than is even to be thought of with the ferrous oxalate developer.

Now, to summarise the judgment on the two methods: one sees at once that the alkaline developer may claim the advantage of more universal usefulness, while the ferrous oxalate developer renders the most excellent service when one has always to work in the same studio. Where, therefore — even when views are taken outside and upon journeys—the plates are always taken to a fixed dark room in which distilled or rain water is at one's disposal, and the temperature never exceeds a certain maximum, the ferrous oxalate developer is in its right place. But there are limitations here. In warm climates it is often difficult to keep the dark room and the solutions cool enough, and the alkaline developer at once steps forward and deserves the preference then as well as from every photographer who must occasionally work in improvised laboratories during journeys. Besides, when sodium sulphite is added to it, it is only inferior to ferrous oxalate in one respect, namely, the instability of the ammoniacal solutions, which continuously lose strength in consequence of evaporation. If this drawback could be remedied the alkaline developer would by its universality supplant the ferrous oxalate developer more and more in course of time.

An effort in this direction is made by the soda developer (which is now gaining so much ground in America), in which the very unstable ammonia is replaced by carbonate of soda, the solution of which remains of the same strength for an unlimited time. This developer also deserves full consideration, since it works without restraining bromide, and imparts to its negatives the character of wet plates without sodium sulphate. One objection only can be raised against it, and it merely has to be taken into consideration when travelling. At a mean temperature of 15° C. carbonate of soda dissolves very slowly in water, and sixteen parts of it require one hundred parts of water. One is, therefore, not in a position to prepare a sufficiently-concentrated solution and must use great quantities of it. Thus: Mr. H. J. Newton uses fully 50 c. c. of a soda solution of about ten per cent. to every 100 c. c. of developer. In the studio this is no very great objection, as great volumes of soda solution can be kept in stock; but, when travelling, that is very burdensome, and to make the solution at the time of using it is generally forbidden by the waste of time it would cause—just like the ferrous oxalate developer. The soda developer, therefore, offers the objection to the traveller of requiring a great deal of room; on the other hand, it offers all the other advantages of the ammoniacal developer, with perfect stability of the solutions in addition.

Under these circumstances it seemed to me advisable to make some systematic researches in order to discover whether some other alkalies which are more soluble in water might not replace the soda advantageously. The most prominent of these is carbonate of potassium, which dissolves about six times as easily in water as that of soda. But the favourable comparison is not exhausted by that; for, while carbonate of soda contains 62·8 per cent. water, pure carbonate of potassium is anhydrous, and acts about three times as powerfully, while, if the saturated solutions be compared, one will find that that of the carbonate of potassium has at least fifteen times the effect of soda, and therefore that, if the potassium salt should otherwise prove suitable for the developer, the bulk of the stock solution one would have to carry about would be reduced to a fifteenth. Another advantage would be united to that. In using ammonia one can vary the quantity of alkali at pleasure; with soda that is hardly possible, as by adding more soda solution the developer would be so much diluted that it would require more pyrogallol. With the solution of carbonate of soda, however, one can work just as with ammonia, though the quantity must be somewhat greater. For instance: if one wished to take the quantity that would correspond to the above-mentioned—fifty c.c. of soda solution, for a normal developer, to every 100 c.c. of water—about three c.c. of the potassic solution would be required—a quantity which could, of course, be increased at pleasure.

For my purpose, in addition to carbonate of potassium, only caustic potash and caustic soda could be considered as being soluble enough in water and of undoubtedly powerful action. In order, therefore, to obtain a complete series for comparison I prepared the following solutions:—

I. Water 100 parts, potassic oxalate 33 parts.
II. Water 100 parts, ferrous sulphate 33 parts, citric acid 0·75 part.
III. Water 100 parts, bromide of potassium 10 parts.
IV. Water 100 parts, alcohol 10 parts, salicylic acid 1 part, pyrogallol 10 parts.
V. Solution of sodium sulphite (1:4) 230 parts, ammonia (0·925) 120 parts, bromide of potassium 40 parts.
VI. Water 100 parts, caustic potash 6 parts.
VII. Water 100 parts, caustic soda 6 parts.
VIII. Water 100 parts, carbonate of potash (purified potash) 90 parts.
IX. Water 100 parts, sodium sulphite 25 parts.
X. Water 200 parts, sodium hyposulphite 1 part.

Emulsion plates of equal size were exposed at a distance of one meter to the light of the burning of 1 c.m. of magnesium ribbon, under a graded photometer 13 c.m. long and 21 c.m. wide, specially constructed for this experiment of fine tissue paper. The photometer was arranged so that each of the twenty-five steps which formed the scale was 21 c.m. in length, and about 0·52 of a centimetre in width. These plates were afterwards cut into narrow strips perpendicularly to the degrees of the photometer, and each strip was then separately developed in 100 c.c. of developer. The average time of development was three minutes; only in the case of the potash developer, to which bromide was added, it was four minutes, and in one instance it was twelve minutes, in order to test the action of prolonged development.

The result given by the above table is that, while caustic potash and caustic soda seem quite unsuitable, the potash developer, as I propose to call it, stood the test quite exceptionally, and, especially when sodium sulphite was added to it and imparted a blue tint to the plates, it quite equalled the ferrous oxalate. But this result would be still more significant if a second series of experiments made by me be taken into consideration. I had a series of plates, prepared according to Mr. Henderson's method, which gave very good negatives with ferrous oxalate, but with ammoniacal pyrogallol showed the most pronounced green fog. These plates behaved faultlessly when developed with potash, and showed only a scarcely-perceptible fog, which remained unincreased even by prolonged development when sodium sulphite was added. In this respect also the potash developer shares the good qualities of the ferrous-oxalate developer—is quite equal to it in every respect, and surpasses it in convenience for use when travelling. It is very remarkable that an increased addition of potash does not produce flat pictures, as one would have expected, but exceptionally powerful negatives clear in the shadows. In the case of under-exposure one must beware of adding *more* potash. The right thing to do is exactly the opposite; while with over-exposure increasing the potash with, in case of need, the addition of bromide of potassium (which should not in general require to be used) produces excellent results. Now the formula which I consider the best is—

I.

Water	100 parts.
Alcohol	10 ,,
Salicylic acid	1 part.
Pyrogallol	10 parts.

II.

Solution 1:4 of sodium sulphite	100 parts.
Potash solution (9:10)	100 ,,

To every 100 c.c. of developer take 2 c.c. of I. and from 1 to 32 c.c. of II., according to the degree of softness or of brilliancy one wishes to obtain. By suitably graduating the developer one can doubtless develope every negative so that it shall not need any intensification. The proportion which, in respect to power, most nearly corresponds to the ferrous oxalate developer is 4 c.c. of potash solution to 100 c.c. of developer.

Finally: a word upon the question of cost. The soda developer is certainly cheaper, since one kilogramme (about 2 lbs.) of soda only costs 25 Pf. (say 2½d.), and one kilogramme of purified potash 1·40 Mk. (say 1s. 4d.); yet the proportion is not really so unfavourable after all, since the potash is three times as effective as the soda. One should, however, not be tempted on the plea of a false economy to use the unpurified potash, which costs only ·70 Mk., or the still cheaper raw product, because the salts of chlorine they contain would essentially retard the development. Also the potash developer is cheap enough, and, in consideration of its great advantages, can confidently step into the chemical-chest with every other one.

Franz Stolze, Ph.D.

SHEFFIELD PHOTOGRAPHIC SOCIETY'S EXHIBITION.

The Annual Exhibition of the Sheffield Photographic Society was opened in the Cutlers' Hall, on Monday last, Jan. 7th, by the Mayor, Mr. Alderman Brittain, who was accompanied by the Town Clerk and several gentlemen connected with the Society. The present collection offers a great contrast to the first attempt made by the Society, two or three years ago, in the same building, when, as we recollect, the rooms had a rather bare appearance, the exhibits being confined almost entirely to members. Now, however, there are upwards of four hundred pictures hung, including many works by our leading artists, both amateur and professional.

The MAYOR, in declaring the exhibition open, delivered an address in which he spoke of the advantages derivable from photography In the course of his remarks he said that he looked upon the art as one inducement to go into the country. By its aid the beauties of nature were reproduced, and, although it was not an absolute necessity that the photographer should be a true artist, yet he should have the feelings of an artist, to select such beautiful views for his work as were exhibited in that hall. The beauty of the picture was not entirely in the composition of it, and many men might note with pleasure a beautiful landscape without knowing much of the principles of art. The means of producing beautiful pictures were within the reach of every Sheffield man. There was no manufacturing town in the world more magnificently situated than Sheffield. He had had the privilege of travelling very much during a part of his life, and had visited some of the most beautifully-situated cities in Europe, most of those which had a reputation for pretty surroundings, and he must honestly confess there was no town in Europe he had had the privilege of visiting where the scenery was more beautiful, or even so beautiful, as that around Sheffield. Moreover, they were only within a comparatively short distance of the delightful Derbyshire dales. Their pencils and brushes might not be able to produce works such as those of B. W. Leader, Boughton, Vicat Cole, or other great landscape painters; but there was pleasure in producing, by the sun's aid, such beautiful pictures as were to be seen on those walls. There was a further advantage in photography—the reproduction of works and everything that was beautiful; likenesses, some of them of those they loved, and those whom in life they recollected. There were so many beautiful objects that he need not particularise; but he would say that anything that took them into the country out of the smoke of the town—be it photography, or any branch of natural history, zoology, ornithology, or botany—should have the support of every Sheffielder, for these studies were not only a means of great enjoyment but of prolonging life. Concluding, he declared the Exhibition open, and wished it and the Society every success.

Among the more noteworthy works exhibited are several of the well-known studies of Mr. H. P. Robinson, including his *Merry Tale* and others from the last two exhibitions in Pall Mall.

Mr. W. McLiesh, of Darlington, also sends his famous *Misty Morning on the Wear* and *Nature's Mirror*, with other examples of his work.

Messrs. Valentine and Sons (of Dundee), Messrs. Adams and Scanlan (of Southampton), Mr. W. England, the Autotype Company, Mr. T. B. Blow, the Rev. H. J. Palmer, Messrs. West and Sons, and Mr. M. Auty (of Tynemouth), are amongst the exhibitors from a distance, while Sheffield and its neighbourhood are well represented.

Dr. T. H. Morton, the late President of the Society, exhibits a number of Indian and other views, as well as photomicrographs. Mr. W. B. Hatfield, the Treasurer, contributes several frames of excellent landscape work, and also several "composition" studies; and Mr. J. Taylor, the Secretary, also exhibits some good landscape work, so that the Society, as represented by its officials, may be considered to have done its duty. Mr. W. Dakin, ex-Secretary, is also represented; and Messrs. W. Davis (of Ripley), Seaman (of Chesterfield), G. V. Yates, W. Turner, T. S. Yeomans, E. Maleham, T. S. Hicks, S. Foxon, and other local names are found in the catalogue.

The show of apparatus and appliances is not large, being confined to exhibits by the well-known firms of Marion and Co,, J. F. Shew and Co., H. Moorse, Lancaster and Son, and Hunter and Sands. Mr. J. Taylor, Secretary, exhibits cameras; Messrs. Cubley and Preston, graphoscopes, &c.; Mr. J. Dyson, an optical lantern; and Messrs. Hibbert Bros. examples of crystoleum painting and materials—these last-named being all local exhibitors.

The Exhibition will remain open until the end of the present week, the evenings being enlivened by lantern and musical entertainments.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

THE third ordinary meeting of this Society for the present session was held at 5A, Pall Mall East, on Tuesday last, the 8th instant,—Mr. James Glaisher, F.R.S., President, in the chair.

The minutes of the previous meeting having been read and confirmed, the following gentlemen were elected members of the Society:—Messrs. A. Tagliaferro and A. G. Dew-Smith, M.A.

The CHAIRMAN said that he had to communicate to the meeting news which had arrived that day, and which he was sure would give pain to every one. It was the death of Mr. J. H. Dallmeyer. He had died within sight of the shores of New Zealand. He was truly loved and respected by all present, and he (the Chairman) was sure that all would sympathise with his family. He had only heard the news recently, and was much affected himself. The loss was not one to them only, but to England and to optical science generally.

Mr. G. L. ADDENBROOKE exhibited a lantern for use in developing and changing plates, especially when travelling. It was exceedingly light and folded into a very small space. It was constructed of three portions, of the material used for book boards, in one of which was a large window of bookbinders' cloth. Any ordinary lamp or a candle could be placed inside it.

Mr. W. E. DEBENHAM asked the exhibitor if he had experimented on any other colours of medium than ruby for a dark room lamp.

Mr. ADDENBROOKE said he had not.

The CHAIRMAN observed that he was always glad to see anything practical, and he was sure that Mr. Addenbrooke's lantern was not only practical but useful.

The discussion was then taken on a paper read before the Society some time ago, by Mr. J. B. Spurge, on the subject of a standard light by which to test the sensitiveness of photographic plates.

Mr. SPURGE went rapidly over the leading points of his paper, which had been read so long ago as six months. The light which he proposed was a white screen, illuminated by four gas jets, each giving a tall flame, the height of which was carefully adjusted. He (Mr. Spurge) also showed a number of plates exposed under his own sensitometer and under that of Mr. Warnerke.

Mr. DEBENHAM said that elaborate mathematical calculations, such as those of Mr. Spurge, were sometimes necessary and useful; but, to be so, they must be exact, and should rest upon an exact basis. If the basis were not exact they were to a certain extent wasted. In this case they rested upon what appeared to him a very uncertain basis. The radical vice of all sensitometers was that they were read by observing the last of a series of tints, which indicated merely what was the minimum amount of light that would affect the plate; but a plate might be made to render such a tint by other means than such as would make it rapid in the camera, especially if it had been exposed to extraneous light. By such means it might be made to show a sensitiveness sixteen times greater than it really possessed. For this reason he (Mr. Debenham) considered that the exact basis on which such a mathematical calculation should rest was wanting. As to the new unit of light: he certainly considered the use of a gas flame to be more convenient than the burning of a piece of magnesium wire and the sensitising of a phosphorescent tablet; but he considered it to be a less sound scientific unit than Mr. Warnerke's. The gas flame might vary from so many causes—the quality of the gas, the barometrical pressure, &c.

The CHAIRMAN suggested the use of a governor.

Mr. DEBENHAM said that the size of the opening might be true to begin with, but that it would become corroded, and that it was even a question if the heating of the burner might not expand it enough to make an appreciable change. All the matters which he had mentioned appeared to him to make the standard a less sound one than that originally proposed by Mr. Warnerke.

Mr. T. SEBASTIAN DAVIS wished to call attention to one point. In the present instance a gas light was proposed as a standard; in that of another sensitometer a phosphorescent tablet was proposed. The question occurred to him, from a mathematical point of view, whether the ratio of sensitiveness between various plates indicated by those two standards would agree one with the other, or would agree with the ratio shown by exposure in the camera on objects illuminated by solar light. He thought that possibly results of practical utility might be gained, but not of mathematical exactness. In his own experience he had often found that a plate which gave a low sensitometer number might give a high degree of sensitiveness in the camera.

Mr. SPURGE said, in reply, that if the effect of pre-exposing a plate were to make it give a higher sensitometer number it would also be to make it give a corresponding result of greater sensitiveness in the camera. He stated that in the burner which he used the hole was circular, one millimetre in diameter, and that any slight variation in the diameter of this hole made much less than a proportionate difference in the intensity of the flame. He said that the quality of the gas might vary by thirty per cent. before any appreciable difference could be perceived in the brightness of the flame, the height being kept constant. As to the ratio of the sensitiveness of different plates being different according as the source of illumination was a gas light, a phosphorescent tablet, or sunlight: he thought that such variations did not exist when the same salts of silver were used. If different salts were employed it would be necessary to introduce a constant for each salt.

The CHAIRMAN thanked Mr. Spurge for bringing the matter again before the Society.

M. G. L. Addenbrooke and Mr. C. R. Woods were appointed auditors for the accounts of the Society; and Mr. W. Cobb, Mr. A. Cowan, Mr. F. Hollyer, and Mr. W. K. Burton were appointed scrutineers of the voting-papers.

The meeting was then adjourne l till the 12th February.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE annual lantern meeting of this Society took place as usual on the 3rd instant in the large hall of the Society of Arts, John-street, Adelphi, it having become the custom during many years past to devote the January meeting to this purpose.

Mr. WILLIAM BROOKS again had charge of the lanterns while Mr. F. A. Bridge, the Secretary and Treasurer, officiated as lecturer and also presided at the piano. The large room was crowded from the platform to the clock by an appreciative audience, who were not backward in applauding the more meritorious pictures as they appeared. The pictures which were most generally admired were those of Messrs. Joseph Gale, York, Brooks, F. Beasley, and the Sciopticon Co. Amongst the principal remaining exhibitors were Messrs. Cobb, Wheeler, Bridge, Ayres, Hepworth, and Brigirshaw.

The interval was, as usual, enlivened by music, the vocalists being Miss Harding, Mr. Page, and Mr. Bridge, the last-named gentleman, as we have said, also filling the duties of accompanist.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Society held on Thursday, the 4th inst., the chair was occupied by Mr. W. E. Debenham.

Mr. W. T. WILKINSON inquired whether any member had tried the method suggested by Mr. Brooks of using the same developing solution continuously.

Mr. A. L. HENDERSON had given a formula for the purpose long ago. He did not think, however, that there was much economy in the plan.

Mr. A. MACKIE had a bottle of developer which after having been used was put away for a year. He found on trial that it still developed, although very slowly. It took an hour and a-half for the purpose, whilst with a fresh solution development was complete in four minutes. As to the quality of the resulting negatives: if anything, it was in favour of the old solution, which gave an appearance the nearest approach to that of a wet plate film that he had seen.

Mr. HENDERSON had made up some developer, two and a-half years ago, containing free bromine. It developed fairly well after long keeping. Referring to the use of an acid alum bath before fixing, he said that if the negative were immersed in the hypo. bath before the above was thoroughly washed out there would be a slight clearing and bleaching action, which proved sometimes very beneficial.

Mr. A. COWAN said that for the same purpose he had used a ten-per-cent. solution of sulphuric acid before fixing.

Mr. MACKIE observed that he for some time adopted this plan, but when doing so he first made the hypo. bath alkaline.

Mr. HENDERSON then mentioned the method of reducing intensity of negatives proposed by Mr. J. Spiller, and consisting of a solution of sulphate of copper and common salt. He (Mr. Henderson), however, preferred the vapour from cyanide of potassium.

Mr. MACKIE had tried solution of cyanide of potassium, and had kept a negative in it for four days without producing any result.

Mr. HENDERSON thought that was owing to want of air. The vapour from the cyanide must combine with air to produce a beneficial action.

Mr. F. W. HART had tried Mr. Spiller's plan for reducing negatives, and found it very nice. Pure cupric chloride acted similarly.

Mr. WILKINSON recommended a solution consisting of nitric acid two parts and saturated solution of alum five parts for clearing silver stains from negatives.

Mr. MACKIE said that sometimes cyanide of potassium would remove such stains, and at other times it would not.

Mr. PARSONS showed a finder consisting of a small camera with a reflector like the old camera obscura; there was also a shade over the ground glass.

Mr. COWAN said that Mr. Harrison had shown a similar one with his camera some time since.

Mr. WILKINSON remarked that some time ago Mr. Ashman had spoken of stains as arising from the developing-dish not being perfectly cleaned out with acid. He (Mr. Wilkinson) preferred to have a new surface by coating every night with a black varnish. The kind he used was called lignosote, which was a very thin liquid.

Mr. HENDERSON then said that if a pinhole were made in a piece of card or brown paper, an object looked at closely appeared to be in focus, but a newspaper held at what was before the proper distance for reading, would be out of focus, and could no longer be read. Why was this?

The CHAIRMAN held that the newspaper was not put out of focus by the use of the pinhole diaphragm, but that so much light was cut off that the small print could no longer be read. There might also be some confusion caused by diffraction and by reflection from the sides of the tube which the pin formed in the card.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

THE Board of Management of this Association held its usual monthly meeting on Wednesday, the 2nd inst., at 181, Aldersgate-street.

The minutes of the previous meeting were read and confirmed. Messrs. Carroll, Dugdale, Cotrell, Dubbin, Logan, and Wilkinson were proposed, seconded, and elected members of the Association.

It was then decided that the annual general meeting should be held on Wednesday, the 30th inst., at 181, Aldersgate-street, at eight p.m. All members who can attend are requested to do so, and members of the profession are earnestly invited.

Correspondence.

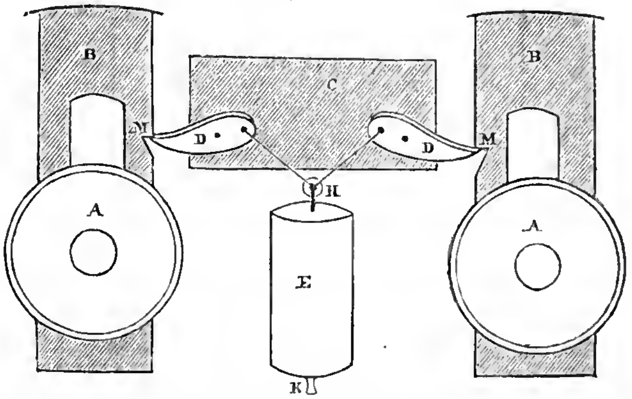
MEETING OF THE PHOTOGRAPHIC SOCIETY OF FRANCE.—LIFE-SIZE PORTRAIT WITHOUT ENLARGEMENT.—A NEW APPARATUS FOR RAPID SHUTTERS.—A DRYING APPARATUS FOR GELATINO-BROMIDE PLATES.—PHOTOGRAPHIC STUDIES: MEDICAL POINT OF VIEW.—LECTURE ON FILMS, BY M. LÉON VIDAL.—ON THE INTRODUCTION OF STARCH IN EMULSIONS, BY M. AUDRA.

THE monthly meeting of the Photographic Society of France was held on Friday evening last, the 4th inst.,—M. Davanne in the chair.

M. CHALOT, successor of M. Franck de Villechole, exhibited the bust of a gentleman, size of nature, taken direct without the aid of an enlargement. The proof was 18 × 24 inches. The result was perfect, and was very much admired by all present. M. Chalot, in answer to questions put to him, said it was obtained by a three-inch aplanatic lens of M. Darlot's, having a focus of forty-four inches. He gave a gelatino-bromide plate an exposure of forty seconds in order to obtain the negative.

M. MAUDUIT presented a new pneumatic apparatus by which a similar exposure can be given with two stereoscopic lenses when guillotine or drop shutters are employed. An india-rubber tube, with air-ball, is put on the instrument at K (see *fig.* 1). By pressing the

FIG. 1.

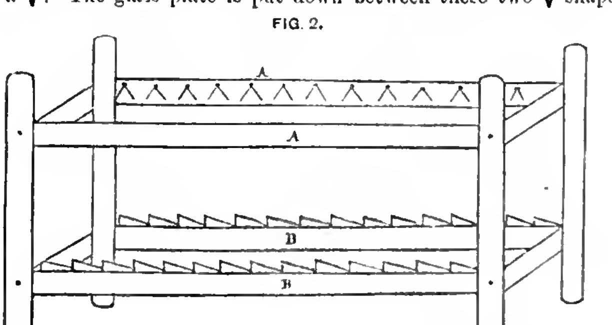


A A, Lenses. B B, Drop shutters. C. Brass plate, to which are riveted the movable levers, D D. E, Cylinder. H, Piston. K, Nibble for india-rubber tubing. MM, Slots in drop.

ball, air enters the cylinders and drives up the piston, H, which causes the movable levers, D, to leave the slots, M M. The steel drops then fall down, and the exposure is finished. Naturally, as can be seen, the exposure can only be regulated by the length of the hole in the drop, or the rapidity of its fall.

M. ROGER presented a drying-stand for the desiccation of gelatino-bromide preparations on glass. It consists of a wooden frame sufficiently long to contain about twelve plates. On the two top cross-bars short pieces of ground glass, about the size of a penholder and about an inch long, are inserted in such a manner as to form an open space like a V. The glass plate is put down between these two V-shaped

FIG. 2.



A A, Cross-bars, in the interior of which are fixed the glass V-shaped pegs B B, Lower cross-bars, to which are fixed the ratched notches to support plates.

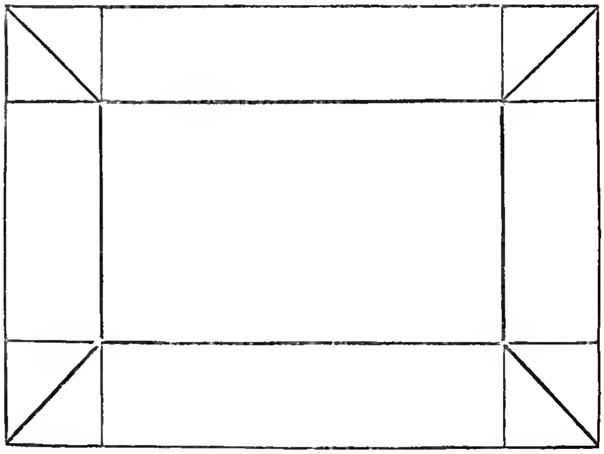
holders, and then falls upon the two lower cross-bars, which are notched to prevent their slipping, and to keep them in their places.

At the bottom of these notches there is a piece of glass, so that the prepared plates do not rest on wood. When one of these plate-holders is full it is carried into the drying-room, where these kinds of frames can be piled one upon the other up to the very ceiling. The air, says M. Roger, can circulate freely and the plates dry rapidly.

M. Londe and Dr. Richer presented some photographic studies taken at the lunatic asylum for females, in Paris. They represented a patient suffering from muscular contractions of the face. Photography had seized and admirably portrayed every expression delineating pain and suffering. M. Londe spoke of the value of stereoscopic pictures. He regretted that this most interesting and beautiful representation of nature was going out of fashion, and hoped that a new impulse would be given to stereoscopic productions by the gelatino-bromide process and new apparatus. He felicitated M. Mauduit on his endeavour towards accomplishing that object. This hope was highly approved of by the President and the members generally.

M. Léon Vidal gave a demonstration upon the value of films for tourists, and counselled the employment of small cameras. He began by saying that he had, like a conjurer, filled his pockets with all that was necessary for an amateur when travelling in order to make photography an amusement and not hard work. M. Vidal then began to empty his pockets of bottles containing developing and fixing solutions, trays, &c. These trays were flat, extremely light, and took up very little space. They were made of ordinary calico or linen cut to the size required, with folds-in, ready to be made into a tray. (*Fig.* 3.)

FIG. 3.



They are made in the following manner:—Take a piece of calico of the size fixed upon for the tray; fold it as in *fig.* 3. and pass a hot iron over the folds to make them indelible. The future tray or trays are then plunged into collodion, and when soaked taken out to drain and dry. When desiccation is complete the linen tray is put into an oven and varnished with a solution of celluloïd. The tray is now impermeable. In order to use it, the sides are raised up and the corners folded. The corners are then nipped by means of a paper-holder or steel spring, and are ready for use. The names of the solutions were written on the bottom of those presented by M. Vidal.

That gentleman then began to fold his trays, and to place the steel springs to hold the corners fast. When this was done, he filled the trays with a solution of alum-water, ferrous oxalate developer, water, hyposulphite of soda, and the last one with water—six trays in all. The two first were not employed, as he was not in a dark room, but in a place inundated with light. He took out of his pocket a piece of ebonite bordered with tinfoil; this he plunged into the ferrous oxalate solution, and, by the aid of a camel's-hair brush, he undid the tinfoil. A film was then seen to appear (which film had been previously exposed), and the development very soon began to bring up the image. In a short time a negative was complete. No precaution was taken to turn down the gas; it was only the red colour of the iron solution which protected the film from fog. No fog was visible. In taking the negative from the ferrous oxalate solution to the washing and hypo. bath the light was a little shaded by the interposition of a piece of cardboard. When sufficiently fixed and washed the film was transferred to a piece of glass which had been previously cleaned with French chalk; blotting-paper was laid upon it, and a small roller passed over its surface, which acted by absorbing the excess of water and making the film negative adhere without air-bells to the surface of the glass. M. Vidal then took narrow strips of gummed paper and bound the negative down to the glass by sticking these bands round the negative —half the band on the negative and the other half on the glass. This negative was passed round, together with others.

M. Vidal then informed the members that, as a precaution, the film, when dry, should be collodionised. Afterwards the collodionised side must be made to adhere to the glass, and the same precaution should be taken to stick the bands of gummed paper round, and collodionise the other side. By this means the gelatine film is enclosed between collodion, which will protect it from damp and danger.

M. Vidal informed the members that the films employed by him for these experiments were the new films of Professor Stebbing. He (M. Vidal) preferred such films—that is to say, loose films ("*pellicules libres*") without any temporary support whatever, such as paper, collodion, mica, celluloïd, &c. If paper films be employed, it is well to tear off the gelatino-bromide film from the paper, and, thus separated, use it as a loose film, for the following reasons:—

1. The development is very easy—much easier than when supported upon paper, &c. No curling up need be feared, caused by the unequal distention of the two surfaces of gelatine and paper.

2. No frilling is to be feared, as the sensitive surface is not in contact with any support, either temporary or permanent.

3. Because the film, being perfectly loose, has entire freedom to extend or expand equally in every direction, and thus an enlargement is obtained which varies in the proportion of 36 to 49.

4. Fixing in the hyposulphite of soda is much more rapid, because the solvent of unreduced silver bromide acts on the back as well as the front of the film containing the silver salts. If the film be fixed in a black tray these loose films have a great advantage over those upon paper, inasmuch as one can easily see if the last trace of unreduced silver bromide be eliminated.

5. These films give sharper definition of the image, and the resulting negative is more brilliant than if the sensitive surface were upon white paper. To prove this assertion it suffices to attach a film to a black surface and another to a white one, give an equal exposure, and develope the two in the same solution. That upon the black ground will be found to be far superior.

How are we to realise the use of films for excursions, &c., and employ our cameras, dark slides, &c.? The solution of this question has been found. Here, said M. Vidal, is a sheet or leaf of thin black ebonite. I now take a piece of diachylon of the same size. I lay it upon the ebonite, the composition side towards the ebonite. I then draw over a squeegee or roller to make the sticking-plaster adhere to the ebonite and to drive out the intervening air. I now damp the back of the linen. I lift up a corner to see if the plaster adheres to the ebonite; if so, I tear off the linen in this way. All can now see that the sticky composition is transferred to the ebonite. The film is laid upon this sticky surface, a piece of clean paper is laid on it, and a roller is passed over it to make it adhere at every point. The film is now ready for the dark slide, offering the double advantage of unbreakability and freedom from halation, not to speak of less weight, &c. These prepared ebonite sheets or leaves can be employed over and over again, as the exposed film can be drawn off it with ease and another film put in its place. If a little plaster adhere to the back it can easily be taken off by a little benzoline or turpentine.

M. Vidal was complimented by the Chairman, and cheered by all the members. The development in full light, under the protecting agency of the iron oxalate solution, had been heard of by some, but had never been seen to such advantage as it was at Friday night's demonstration. In fact, I was asked if I introduced anything into my films to give them immunity from fog.

I must here state that M. Vidal, during all the manipulations, took great care not to touch the film with his fingers. He passed under the film a kind of shovel made out of a piece of celluloïd, and coaxed the film upon it by the aid of a camel's-hair brush.

M. Audra informed the members that he had been experimenting upon divers substances in order to obtain a greater rapidity in gelatino-bromide of silver emulsion. Among other things he had tried starch, and had found that the introduction of the latter into the emulsion did not make it more rapid, but gave a very peculiar effect to the finished negative; it caused it to have the appearance as if the emulsion had been spread upon ground glass. M. Audra showed several positives by contact-printing, which had a very pretty effect. He (M. Audra) informs those who wish to experiment in this way that the emulsion must be well filtered before the starch solution is introduced; the emulsion is then heated until the starch becomes a jelly in the midst of the emulsion.

E. Stebbing, *Prof.*

25, *Rue des Apennins, Paris, January* 7, 1883.

PHOTOGRAPHIC EXHIBITIONS.

To the Editors.

Gentlemen,—The simple and childlike innocence of your correspondent "Bristolite" is perhaps, like the signature, assumed, as he points with such *empressement*:—"You see there is no deception about this; the names are not on the *front* of the exhibits, consequently nobody knows where they come from, and there is no possible source of information besides." Of course not, but let that pass.

I have already said, and again repeat, that it seems a great mistake for the hangers and judges to work independently of each other. Another mistake is to have the medalled pictures placed in bad positions and in out-of-the-way corners. That, if both the hangers and judges worked together, would not be likely to occur. As it is, pictures sent in and got up at considerable expense and trouble are entirely at the mercy of irresponsible persons (whose names are not published), to be kicked out or hung on the line, just as it happens, with charming impartiality.

The instance I gave of pictures being rejected at Pall Mall and medalled at another exhibition is a conclusive argument that exhibits are not hung on their own merits. That, I contend, they should be; and, whether I show good or bad taste, it is an example to the point. In a photographic exhibition, *unless the room be insufficient*, it is a moot point if *all* photographs sent in should not be hung. There are many strong arguments in favour of it. Of course, if the space be too limited for all, the worst should be weeded out; but this operation *ought to be performed by those appointed to judge* the merits of the works, and not by irresponsible persons who are supposed to have no care but that of fitting the frames together on the walls of the rooms.

These are points to be considered at future exhibitions, and which, if adopted, may possibly lessen the dissatisfaction to which all our exhibitions have hitherto given rise.—I am, yours, &c. EDWARD DUNMORE.

January 7, 1884.

TRAVELLING LANTERNS.

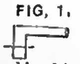
To the EDITORS.

GENTLEMEN,—Your correspondent, Mr. W. H. Harrison, asks for information as to any good *flexible* material for the light of a *travelling lantern* for changing plates and development. He cannot do better than use Thomas's flexible ruby tissue. It looks like oiled silk, gives a beautiful light, and is perfectly safe for *quick* plates. I have used it for some time for changing Wratten and Co.'s *instantaneous* plates at night, in bedrooms of any place at which I am stopping.

My lantern is constructed on this principle (exactly like the little sketch given at page 125 of your ALMANAC); but I started on the basis of convenience in packing, in this way:—I had a tin (triangular) box made just

FIG. 2.

FIG. 1.



Movable chimney to place over hole.

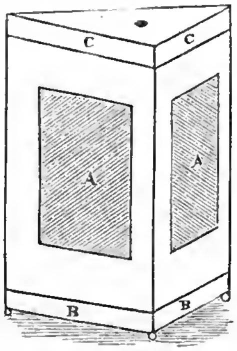


FIG. 3.

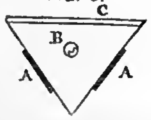

Section.

Fig. 2. A, Thomas's ruby fabric. B, Bottom of box. C, Lid of box.
Fig. 3. A, Ruby light. B, Candle. C, Solid pasteboard backs.

the size to cover my tripod-head when shut up inside it. This, when separated (lid from bottom), forms the bottom and top of my lantern, and in it I set up the folding, strong pasteboard sides of the lantern. Provision is made for ingress and egress of air for combustion of a piece of sperm candle.

The joints are made of cloth glued on and covered with a strip of the ruby fabric to make it safe, and when set up for use I close the joints at top and bottom by a broad piece of elastic braid sprung on, which tightens up the lantern and holds all well together.

The advantages are:—When unpacked the lantern occupies very little space, as it folds up quite flat, in the same size as the folded camera body and slides; the top and bottom take little more space than is necessary for the carriage of the tripod-head.—I am, yours, &c., LUX.

January 5, 1884.

DARK ROOM LIGHT.

To the EDITORS.

GENTLEMEN,—I have just seen an article by Mr. G. D. Macdougald on this subject in your last issue, in which he refers to an article of mine in the previous number.

I regret that I did not see his article in time to reply to it this week, but I hope to go into the matter fully next week, and will be most happy if he will join me in a series of experiments on the subject, which, I think, is a most important one, because the tone equivalents (or, in other words, the depth of tint in a photographic film) of different coloured surfaces are, of course, the groundwork of practical photography.—I am, yours, &c.,

Grange Park, New Thornton Heath, HERBERT S. STARNES.
January 7, 1884.

NEWTON'S IODO-CHLORIDE OF MERCURY ACCELERATOR

To the EDITORS.

GENTLEMEN,—Immediately after perusal of the notice of the new accelerator I prepared some of it, carefully following Mr. Newton's formula. On experiment I found that positives and negatives came up with startling celerity, and that plenty of density was obtained, without fog, in a very short time. But the colour! My transparencies of buildings are all yellowish-green. My negatives look horribly bilious. In the course of my experiments I have obtained yellow, red, and other coloured negatives, but this colour never before. Does the experience of others coincide?

The plates used were Nelson's 10 times and Fry's. The developer consisted of commercial carbonate of soda, good pyro., and no bromide. The carbonate of soda *may*, and probably does, contain sulphate, but will not materially differ from the average commercial soda carbonate.—I am, yours, &c., HENRY POCKLINGTON.

Leeds, January 8, 1884.

A PHOTOGRAPHIC WANT.

To the EDITORS.

GENTLEMEN,—Probably many besides myself get waste glass plates when travelling, and if any collodio-chloride emulsion were in the market which would give good lantern transparencies by simple treatment with the ordinary sulphite or iron developer in use for negatives, the waste glass plates would be used for the purpose, and the emulsion be in demand. In advertisements I cannot find a notice of any emulsion which professes to meet these conditions.—I am, yours, &c., W. H. HARRISON.

Hotel du Lac, Lucerne, January 8, 1884.

ENAMELLING.

To the EDITORS.

GENTLEMEN,—Referring to Mr. A. L. Henderson's lecture and your own editorial remarks on *Ceramic Photography*, will you kindly help me with a few queries?

I may state that some years ago I did all the manipulations in photo-enamelling (except burning) for one of our leading photo-enamellers, but that all the formulæ were kept from me. Then I used the substitution process (collodion transparency); but, in commencing photo-enamelling in good earnest again, I should much prefer not having to keep going a wet bath, so I intend trying the "dusting-on" process:—1. Neither in Mr. Henderson's article or your own can I find any definite formula for the sensitive medium which is to be poured over the first coat of collodion, unless you mean to convey that Poitevin's is still as good as any. In the others to which you refer can you name a reliable one?——2. You say "finely-powdered enamel colours are next dusted." Where are these procurable? and what colours would be best for first experiments? I think the experimentalist should know, too, their ingredients.——3. You give instructions for toning, but does not this apply only to cases where the image is composed of *silver*? or does it apply to the dusting-on process as well?——4. In the dusting-on process is the toning done before or after the film is floated?——5. With the collodion transparency I used to "fix" it with ammonia solution (why I don't know). Is any "fixing" necessary with the dusting-on process beyond the "rinsing" you mention?——6. Is the "rinsing" above alluded to for facilitating the removal of the film from the support, or for some other reason?——7. For facilitating the removal of the film Mr. Henderson seems to use sulphuric acid (I have found the same very efficacious), but why does he saturate with boracic acid, I wonder?——8. Where can I obtain the "flux" or "glaze?"——9. Is there any reason why gelatine should not give as suitable a transparency as collodion?——10. Mr. Henderson says one of the secrets of photo-enamelling is to put the glaze on the plate *first*. I am wondering if "first" means before the *plaque* is heated at all; if so, Captain Abney recommends the reverse.——11. Will the sensitised plates keep so that a number may be prepared all ready for use?——12. I fear I am ungrateful in questioning whether Mr. Henderson said all he might on little points upon which he knows success or failure greatly depends. If he has, is he not a generous man? His fee for private instruction is fifty guineas!—I am, yours, &c., J. BERRYMAN.

Rembrandt Studio, Redhill, January 2, 1884.

[In reply to these various queries:—1. Either of the three formulæ first given on page 227 of the ALMANAC for this year may be relied on.—2. Try James How and Co., Farringdon-street, London.—3 and 4. No toning is necessary when employing the dusting-on process.—5 and 6. No.—7 and 8. We cannot tell.—9. Yes.—10. The meaning indicated is correct.—11. We have never tried the long keeping of plates prepared for dusting-on.—12. This is a matter in which each is at liberty to form his own opinion.—EDS.]

Notes and Queries.

WILL any reader acquainted with the facts be so kind as to inform me of the relative remuneration given to fairly good artists in America, either in the United States or Canada, and in England?

IN constructing a glass house for portraiture is there any practical advantage in having the glass arranged approximately in a circle of which the sitter is the centre? I know that according to pure theory this is best, but am desirous that anyone having a practical acquaintance with the subject would give me an opinion.—X. Y. Z.

I HAVE a strong desire to be able to attach the significant letters "Ph.D." to my name. I have been informed that if I can give a certificate of good character and fair attainments in physical science I can, on application, receive the degree to which I aspire. Will any reader enlighten me as to the steps necessary to be taken, stating the fees, place of application, and giving any other information?—ASPIRANT.

IN reply to A. P. F., in *Notes and Queries:* let him try the effect of adding a little tannin to the gelatine. In reply to G. S. Robertson, who inquires if he be not at liberty to exhibit in the lantern engravings taken from a book purchased in the regular way: Although a case of this description does not appear to have been anticipated by the framers of the Copyright Act, I am of opinion that he could not be legally prevented from doing so if he feel so inclined.—LEX.

GENTLEMEN,—I have much pleasure in answering the query by the Rev. G. Morse in your last issue; but if he had referred to my papers on *Astrono-*

mical Photography, published last year in these pages, he would have found the information required. I know of no *rules* by which the *chemical* focus can be found. Its place depends, of course, on whether the lens is *over-* or *under*-corrected. The moon is the best object to try upon. The telescope tube should be marked when focussed for the visual image; then trial plates must be exposed after drawing out the tube (say) one-eighth of an inch or less, until the true chemical focus is found. If lengthening the tube give worse results the reverse plan must be adopted, and when the proper focus is found the tube may be marked, and that always afterwards will be *near* the proper place.—A. BROTHERS, F.R.A.S.

IN reply to the query of Rev. G. Morse, in last Journal, I beg to say that by separating the crown and flint lenses of a telescopic object-glass the foci can be made to coincide at any rate to this extent: that the sharpest plane of visual representation may also be rendered the sharpest plane for photographic delineation. There is no rule by which this coincidence can be secured—nothing but by repeated trials. But here lies the objection to this method of assimilating the chemical with the visual foci:—In proportion as you separate the lenses, so do you impair its capability of defining sharply. In ordinary practice the best way of obtaining definition is to ascertain, by very careful measurement, the distance between the two foci and make allowance for them, by having a dark slide specially constructed, and in which this difference is recognised.—W. H.

Exchange Column.

I will exchange a $2\frac{1}{4}$-inch portrait lens for a folding camera, $8\frac{1}{2} \times 6\frac{1}{2}$ or $4\frac{1}{4} \times 3\frac{1}{4}$.—Address, B. C., 2 York-street, Covent Garden, W.C.

I will exchange a $2\frac{1}{4}$-inch portrait lens for an $8\frac{1}{2} \times 6\frac{1}{2}$ or $4\frac{1}{4} \times 3\frac{1}{4}$ camera, folding for dry plates.—Address, C. D., 8, High-street, Kington, Herefordshire.

I will exchange my sciopticon lantern, quite new, for good standard lantern slides.—Address, LEATHER, photographer, River-street, Bedford Leigh, Lancashire.

I will exchange a large number of copies of THE BRITISH JOURNAL OF PHOTOGRAPHY for anything useful.—Address, A. J. B., 17, Hindon-street, Pimlico, S.W.

I will exchange a good showcase, head-rest (Harrison's), and a 14×11 glass dipping-bath, in pine case, for a whole-plate or 10×8 camera; photographs sent.—Address, O. E., 19, Station-hill, Kidderminster.

I will exchange a half-plate bellows-body camera, Dallmeyer's stereo. lens, and dark tent, new, for a good half-plate bellows-body camera and rectilinear lens.—Address, H., 90, High-street, Upper Sydenham, S.E.

I will exchange a luxographic lamp for taking portraits by night, in good working order, for a cabinet burnisher, fur rug, and interior or exterior background; or offer.—Address, M. GWINN, Photo. Artist, Newport Pagnell, Bucks.

I will exchange a splendid quick-acting whole-plate portrait lens, by Horne and Thornthwaite, three inches diameter, condition equal to new, for a No. 4 landscape lens, by Dallmeyer, or 12×10, by Ross.—Address, W. H. SEDGWICK, South-view, Sedbergh, Yorks.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

PHOTOGRAPHS REGISTERED—

William James Hunter, Scotch-street, Armagh.—*Three Photographs of Lord Rossmore and Party, taken at Rossmore Park, Monaghan.*

J. W. B.—The reflector showed the concave, the curve being a portion of a true circle.

H. BARSTOW.—Refer to the table on page 260 of our ALMANAC. That will give you the desired information.

H. J. T.—Increase the sensitising-bath to at least forty-five grains to the ounce, and you will, no doubt, proceed more satisfactorily.

WARDEN.—The only fault we can see in the negative forwarded is that it is *very* much under-exposed. The plate appears to be of good average quality.

A. J. GRIFFITHS.—The best material of which you can make your tank is slate. We certainly should not advise you to have metal of any kind. Large earthen pans answer the purpose very well for washing prints.

T. B. CONDER.—The reason you cannot get the albumen clear is that you whisked it too much when you added the acetic acid. Had you followed the instructions, as given, you would have experienced no difficulty whatever.

J. W.—The collodio-bromide process will answer admirably for opal enlargements, though it will be found slower than wet collodion. The development may be performed either with pyro. and ammonia, or with ferrous oxalate.

A. W. BOYD.—For the purposes you require, the lens designated "B" on your list will be the most useful. Next in order comes "A," and then "D," "C." The others will be of very little use to you, as their places are well filled by the others.

A. SICARD.—We do not quite see in what way we can aid you. There certainly appears a considerable difference between the prices mentioned, but to estimate this more completely you should obtain quotations for articles of a precisely similar quality.

H. MASON says he has a quantity of old films washed off collodion negatives, and asks if they are worth reducing to recover the silver?——Certainly they are, and they will yield a very good return. This may easily be proved by fusing a little of the films (after burning them) under the blow-pipe with a little borax.

LUX.—You can test the gas for sulphuretted hydrogen with acetate of lead paper. We advise you to put a ventilator in the room close to the ceiling, which will carry off the fumes, and at the same time you might try different burners. It is quite possible that the burners you now have do not ensure perfect combustion of the gas.

W. D. J. (Leeds).—The transparent spots are due to air-bubbles adhering to the film during the development. In future use a broad camel's-hair brush to remove them.

INQUIRER.—The new patent law will not allow you to patent anything that has been done before, even if it has not been patented or worked commercially. Under the new Act, as under the old, an invention to be patented must be new and original.

AMATEUR PRINTER.—The mealiness of the prints arises from your toning-bath being too new. The acetate toning-bath should not be employed directly after it is made, but should be prepared at least twenty-four hours beforehand. The strength of the fixing solution is quite correct.

A. G. HOPKINS.—You will have no difficulty in procuring basil leather from any leather merchant or dealer in bookbinders' materials. Probably, any bookbinder in your neighbourhood will supply you with the small quantity required for your bellows. The imitation basil will be sufficiently good for your purpose, being cheaper, lighter, and more uniform in thickness.

DEMARR.—A two-fold purpose is subserved by having the lens-mount constructed in the manner described. First, by having the draw-tube portability is ensured; and, secondly, by enabling the stop to be brought nearer to the lens the circle of delineation is increased. This latter quality is obtained at the expense of marginal definition, to secure which the size of aperture in the stop must be reduced.

S. SIBLEY.—The curious marking on the collodion plate, which you describe as being "like as if a worm had crawled over the plate and left a dark mark behind," is caused by an air-bubble in the developing solution. If there are any air-bubbles in the iron solution when it is on the plate these markings are almost sure to be produced, and the curious forms they have are due to the motion they take when the solution is flowed backward and forward on the plate.

W. W. R.—The opaque spots on the negative are due, in your case, to the same cause as in that of many others, namely, that the whole of the hyposulphite of soda was not thoroughly removed from the gelatine film before the plate was varnished. Consequently, the silver in the plate has caused the spots, notwithstanding a film of varnish intervened. Varnish, however good, is not a sure protection in such a case as you appear to imagine, and as your experience proves.

A BERKSHIRE PHOTO.—As some of the prints which have faded have been kept unmounted, while others which are mounted have not faded, we do not see how you can for a moment believe that the mounts are at fault. Neither can you, we think, suspect the starch you have used. Why not suspect the manipulations? They are far more likely to be at the root of the evil than either the cards, the mountant, or the albumenised paper.

W. MANDON.—Shake the bitumen up with the benzole and allow it to digest for two or three days. Then decant the clear portion, and keep it as a stock solution to be diluted as required for use. As different samples of bitumen vary considerably, it is impossible to give any definite strength as being the best. A very few experiments will easily settle the point. You must bear in mind that the thinnest possible film on the plate is all that is required. Many fail with the bitumen process through having the film too thick.

J. S. TOOK.—If the parcel was lost during transit through the post the authorities will not recoup you. Had you, however, sent by rail, or through any of the carrying agents, you might have recovered its value. In future when you have a parcel of great value—such as a painting—you will do better to forward it direct by rail. For a small extra charge the railway company will ensure the safety of parcels for larger amounts if declared at the time. Without a declaration of value at the time of booking the amount that can be recovered in case of damage is limited.

G. T. GRAMMER says:—"In order to make a longer exposure with dry plates on landscape subjects with a rapid rectilinear lens, I have been in the habit of using the smallest stop $\frac{f}{40}$, which, with Swan's plates of 10 times rapidity, allows me to give an exposure of about two seconds on a bright day—open landscape. What I desire to know is, does the picture suffer in any way (say) with regard to atmospheric effect, perspective, &c., by using such a small stop? Or would it be better (if definition be correct) to use a larger stop and swing-back if necessary, of course making a proportionately less exposure? I shall be glad if you will favour me with a reply through the medium of your valuable Journal. I have read all the recent articles on lenses and stops, but cannot find anything to touch my case."——In reply:—The stop here mentioned ($\frac{f}{40}$) is much too small to enable the best effects to be obtained. The practice of the ablest landscape photographers is invariably to employ the largest stop by which the requisite definition can be secured.

RECEIVED.—"Omega;" J. Gloag. In our next.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 16th inst., the subject for discussion will be *On Gelatine Plates for Lantern Slides for Camera Exposures.*

LONDON GAZETTE, *Friday, January* 4, 1884.

BANKRUPT.

ROBERT SNOWDEN, 12, Brook-street, and 17, Castle-street, Hull, photographer and furniture broker, late a toy dealer.

CONTENTS.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1237. Vol. XXXI.—JANUARY 18, 1884.

FERRIC AND FERRIC-POTASSIC SULPHATES.

Ferric sulphate or, to employ a title more familiar to photographers, persulphate of iron has not hitherto found any very serious applications in connection with photography. In the days of collodion positives it was, indeed, recommended as an addition to the developer for the purpose of giving a whiteness to the deposited silver; but it is rather in the character of one of the products of the oxidation of the iron developer that our readers will have more frequently met with it.

About three years ago, however, at one of the meetings of the Photographic Club, Mr. Warnerke mentioned persulphate of iron as a possible reducing agent for over-dense negatives, in virtue of its solvent action upon metallic silver. Since that time but little attention has been paid to the matter, probably owing to the fact that, while reducing the density of the image, an unpleasant stain of more or less depth is, under ordinary circumstances, left in the film. There are, moreover, other possible applications for this salt which may render it worth investigation.

Ferric sulphate is obtainable in two forms—the hydrated and the anhydrous. The former is a dirty yellow, deliquescent mass, difficult, if not impossible, of crystallisation and extremely soluble in water. The latter—which is formed by submitting the hydrated salt to heat until the water of combination is driven off—is obtained as a buff-coloured powder, dissolving slowly and to a far less extent in water. Those who are unable to procure the salt may readily make it in the following manner:—To a strong solution of ferrous sulphate or protosulphate of iron add an equivalent of sulphuric acid and well mix. Now drop in cautiously strong nitric acid until the liquid ceases to blacken and no more nitrous fumes are given off. After filtration the resulting deep red solution consists of persulphate of iron.

This solution possesses some peculiar properties which render it in many ways useful. It is, as has been said, a solvent of silver. If metallic silver be boiled in the solution of ferric sulphate it is vigorously attacked, the liquid at the same time losing its clearness and depositing a yellowish sediment, which consists of a basic ferric sulphate. If the solution of ferric sulphate be strongly acidified with sulphuric acid, the formation of this sediment is almost, if not entirely, arrested, the solvent action upon the silver, however, remaining intact.

If now the clear solutions (filtered, if necessary, after boiling with silver) be placed aside in a couple of tall precipitating glasses, it will be found in a few hours' time that the acidified solution has deposited the whole of its silver in the metallic state in perfectly-white crystalline spangles of great beauty. The neutral solution (filtered while still hot) shows less tendency to deposit its silver, though it does so to some extent. Any scratches on the interior of the glass will be found to attract a deposit of metallic silver, but the bulk of the dissolved metal remains in solution.

This curious effect of solution and subsequent reduction of the silver appears to be due to the spontaneous change that occurs in the somewhat unstable ferric solution, in the course of which the latter becomes a reducing agent.

Very similar in its action, as it is in constitution, is the ferric-potassic sulphate, which is formed by mixing in equivalent proportions ferric and potassic sulphates, when the double salt crystallises. This is well known under the name of "iron alum," or, more definitely, as "potassium iron alum;" for there are similar compounds of iron with ammonium and sodium which also bear the generic title from their resemblance in composition to the real alums. Iron alum crystallises in precisely the same form as common alum, which it closely resembles in taste and sometimes also in colour (or absence of colour), though usually it possesses a pale brownish-pink tint. Upon dissolving in water, which it does with great readiness, the solution strikes a deep red colour, from which, on evaporation, the salt re-crystallises with the same faint tinge of brown, a quantity of basic iron salt being thrown down in the course of the operation. Indeed, so unstable is this combination in its normal state that a temperature very much short of boiling point suffices to decompose it. If, however, it be acidified with sulphuric acid, it may be heated without decomposition.

In general behaviour this solution acts in a manner precisely similar to ferric sulphate in every respect; but, as it is very much cheaper, that will prove an element in its favour should any permanent use be found for either.

The action upon a photographic image is in perfect accord with what has been said in connection with metallic silver. A saturated solution of anhydrous ferric sulphate (which is probably about twenty grains to the ounce), or a solution of similar strength of iron alum, will almost immediately attack the image, dissolving the silver completely, and, so far as that metal is concerned, removing the picture. But it does not entirely obliterate the image, for a faint yellow picture remains behind, however long the application may be continued, together with a yellow stain over the whole film. This ghostly image appears to consist of basic ferric sulphate, which is substituted for the silver; in fact, the image is converted from one of silver to one of iron. Treatment with sulphuric, hydrochloric, nitric, or other acid will remove both image and stain, though these are not applicable to gelatine films. In weaker solution the action is, of course, slower and not so complete, and the stain produced is not so prominent.

Another application suggested to us by Mr. William Bedford is that of acting upon the unfixed picture in order to produce a duplicate negative in one operation, after the manner of the nitric acid process, which is inapplicable to gelatine. On putting this to the test, however, we found it fail on account of the deposition of the basic ferric salt, of which we have spoken above, in the place of the dissolved silver image. The result at first startled us; for, combined with the inevitable stain, so great is the resemblance in colour between the ferric salt and the undissolved silver bromide, that the effect appeared to be the re-conversion of the metallic image to the state of bromide, the film after treatment exhibiting no signs of an image of any kind. By treatment with dilute hydrochloric acid, however, it became faintly visible from partial solution of the ferric salt.

If any means can be discovered of preventing or removing the objectionable stain, ferric sulphate will form the most useful reducing agent for negatives that we have, acting as it does directly upon the image. For other purposes, where a solvent of silver is required, it will also find uses, as for the purpose of cleaning dishes and other vessels and in recovering some descriptions of residues. Other combinations of ferric sulphate we have not tried, but there is no reason to suppose they will behave in any way differently from the potassium double salt.

FUMING SENSITISED PAPER.

Among the subjects which were prominently brought forward in the course of the discussion upon Mr. W. M. Ashman's lecturette, at the meeting of the London and Provincial Photographic Association on Thursday in last week, that of the ammonia fuming of albumenised paper occupied a prominent place. Whether it was during his residence in America that Mr. Ashman acquired a knowledge of the properties and advantages of the ammoniacal treatment we are unaware, but of one thing we are certain, namely, that in this gentleman it has an earnest advocate.

It is so well known as to need no reiteration that the fuming of paper is, in America, a recognised department in the routine of ordinary silver printing, whereas in England it is practised by comparatively few. We shall not here go back so far as to inquire into the reasons by which Mr. H. T. Anthony, the originator of the system of ammonia fuming, was first induced to adopt it, but shall accept the situation as it now exists. One of the most singular things in connection with the matter of fuming is that of its being considered as a necessity in one country and one which is quite a matter of indifference in another. When visiting the great printing establishment of Messrs. Elliott and Fry last autumn—an account of which was published in our issue for October 5th, 1883—we made special inquiry as to whether the paper used by them in printing was fumed. They had not, we were told in reply, considered it desirable or necessary to adopt it. This is also the experience of many others who conduct printing operations in this country on a large scale. We look in vain through the published accounts of the printing process as carried on by England, of London, and Wilson, of Aberdeen, for any allusion to ammonia fuming; indeed, in the work on *Silver Printing: its Difficulties and their Remedies*, by "Aliquis" (Mr. A. J. Wilson), whose connection with the great Aberdeen printing establishment was of the most intimate practical character previous to his removal to London and taking up the high position in the world of letters he has since done, no mention of fuming is made.

That ammonia fuming possesses certain advantages well recognised by nearly all American and a few English photographers there exists no room for doubt. In America no printer would so much as think of conducting his printing operations without fuming; and this being the case we turn to the ablest exponents of the practice in that country to give us the reasons for this preference in manipulation. These advantages, when briefly summed up, are—increased sensitiveness, a richer tone, and a smaller expenditure of gold to obtain that tone than when fuming is omitted.

But even among American authorities there are some who do not display an overweening amount of enthusiasm respecting the existence of the alleged virtues of fuming. For example: the well-known author Professor Towler, in his work, *The Photographer's Guide*, says:—"When the sensitised sheets are perfectly dry they may be submitted or not submitted to the fumes of ammonia, just as you feel inclined about the matter. The advantage of fuming is, after all, not very great, and the finished print is equally good whether the sensitised paper was fumed or not." This, it will be observed, is decidedly non-committing, and shows at anyrate that at the date of his writing as above (1866) this gentleman was not enthusiastic in the matter. A later writer, Mr. Charles W. Hearn, in a work entitled *The Practical Printer*, speaks of the merits of fuming in a much more decided tone. He claims for it certain definite advantages, such as these—that the paper prints richer, quicker, and more brilliant, while the prints tone easier, and the finished pictures are much more pleasing and satisfactory. These claims, we may observe, are those which are still made on behalf of ammonia fuming.

Not until the paper is thoroughly dry must the fuming be proceeded with. In a common wooden box, or close cupboard, of sufficient dimensions, the sensitised sheets of paper are suspended in such a manner as to allow their surfaces to be exposed. At the bottom is placed a saucer containing four or five drachms of ammonia, the fumes from which are allowed to rise somewhat evenly, by covering the vessel with a sheet of perforated zinc or board covered, in some cases, by a thin layer of cotton wool. To obviate the tendency of the paper to become yellow or otherwise discoloured, a little chloride of lime is frequently introduced into the cupboard or fuming box. This discolouration is much more apt to take place during damp than dry weather. When the weather is very cold, a heated brick is placed on the bottom of the fuming cupboard with some advantage. No hard-and-fast rule can be laid down for fuming, but from ten to fifteen minutes may be considered as sufficient.

The precise duration of the exposure to the ammonia fumes must be determined by a variety of circumstances, such as the temperature, the light, and the class of negative to be printed from. American authorities seem to agree that a longer fuming is required for paper sensitised on an acid bath than on a neutral or alkaline one. Weak negatives also require more fuming than strong ones; less fuming being necessary on a dark than on a bright day. This is a matter the proper regulating of which requires practice and experience. From the remarks of Mr. Ashman at the meeting of Thursday week, we also infer that a more brilliant print will be obtained from a weak bath with fuming than from a stronger bath without it.

The fuming of sensitised paper is so easily accomplished as to give little or no trouble to anyone desirous of trying it; we shall, therefore, hope to learn that many of our readers have placed themselves in a position to be able to say from tentative experiment to what extent it is likely to prove beneficial in their own practice.

COMBINATION PRINTING.

In the article on this subject, last week, we described the plans usually adopted when a background has to be printed-in, either as a plain one or one from a second negative; but it is clear that the same principle of masking can be applied to the production of combination prints from different negatives. Indeed, it is the method followed by many artists, who have achieved considerable success in the production of *genre* pictures in which several negatives had to be employed.

There is another plan of combination printing by which, with skill, very artistic results can be obtained. Instead of the image being masked abruptly it is shaded off, so that the impression from one negative is, so to speak, vignetted into that from another. This was the method adopted by the late Mr. O. G. Rejlander in the production of his famous picture, *The Two Ways of Life*, in which, if we are not mistaken, over thirty different negatives were combined. We have an impression that the actual number was thirty-six. Mr. Rejlander covered up all the paper to preserve it from light, except the part under the negative. Then so much of the negative as was not required was shaded off while it was printing, so that no sharp outline was ever produced, as must always be the case with the more common method of masking. When one negative was printed the next was taken in hand, adjusted in position, and then judiciously shaded like the previous one, so that the juncture of the two in the print was vignetted into each other. If by chance the juncture should happen to show, through its being too light, Mr. Rejlander had a very ingenious method of remedying it, which he facetiously termed "touching it up with the pencil of light." This he did by bringing the sun's rays to bear upon those parts which were too light with a condensing lens, used *à la* burning glass—but, of course, avoiding the burning focus—while all the other portions of the picture were covered up.

Mr. Rejlander was very skilful in manipulating the sun's rays with a lens. We remember once seeing an ass's head in outline on a white ground, which he had produced in this manner on a piece of albumenised paper. This novel sketch he humourously entitled a portrait of some of the critics who had written unkindly of his large combination picture.

Now, the masking-in of backgrounds or combination printing from several negatives in silver, where the progress of the work can be watched as it proceeds, is an easy matter compared with doing the same in carbon, or making combination negatives or transparencies by any of the processes usually employed for the purpose. In these processes the result of the labour cannot be seen until the picture is finally developed, when, as a matter of course, if an error in masking has been committed it is too late to apply a remedy; consequently the work has to be gone through afresh. However, combination printing can be successfully accomplished in carbon or, indeed, in any other process.

The most simple form of double printing in carbon is the production of the toned margins to "chromotype" portraits. For this purpose specially-constructed registering frames were constructed, but we believe they are now seldom used. Here is a simple plan by which the same end may be obtained with certainty. The principle involved—which, by the way, is similar to that employed by lithographers for securing an accurate "lay"—may be applied in securing registration in all other processes; so we shall give it in detail. In the first place, a templet with an opening—say, for example, an oval—of the size suitable for the portrait is required. This may be made of cardboard, or, better still, of thin sheet zinc. Now take a piece of opaque paper, somewhat larger than the templet, and on it near one corner, which we will suppose to be the top left-hand one, rule two fine pencil lines at right angles to each other. A pencil drawn along the side and top of the templet is the best plan of doing this. Then adjust the templet so that its top and left-hand side just touch the two pencil lines, hold it firmly in position, and with a sharp penknife cut out the opening. The mask thus produced is now fixed on the negative with a few touches of gum or india-rubber solution. The negative is then ready for printing from.

We now require a tinting mask. For this we take a piece of glass and on it cement, with india-rubber solution, a piece of opaque paper, and on that rule a couple of pencil lines, as we did on the mask for the negative. The templet is then adjusted to them, and the paper cut through as was done in the previous case, but the oval must not be removed from the glass. We now require another templet of the same outer dimensions as the former one, but with an opening corresponding with the size required for the tinted border. This templet is then adjusted to the lines and its opening cut through. All that now remains is to remove the paper from the glass which is between the cuts made with the two templets, leaving the oval blank still adherent to the glass. On the opening thus made can be fitted any design or imprint that may be desired.

Now, it is clear that the oval opening in the mask upon the negative and the blank upon the glass must bear the same relation to the pencil marks or register lines. Consequently, it follows that if a print be made from the negative with the tissue adjusted to the lines, and is then removed and adjusted to the lines on the tinting mask, that portion of the tissue which was before exposed will now be covered, and *vice versâ*. In practice it will be found convenient to gum a couple of strips of cardboard on to the registered lines, so that the tissue or templet can be pushed against them, and accuracy of registration more easily secured than when it has to be adjusted to simple pencil marks.

In double printing, or masking-in backgrounds into large pictures, instead of having pencil lines or cardboard against which to adjust the tissue, the sides of the pressure-frame, or even the edges of the negative itself, may be more conveniently utilised as a means of registration. Here is a method which we happen to know is largely employed in printing-in backgrounds to carbon enlargements:—First, while the enlarged negative is on the retouching desk, a piece of tracing-paper is placed upon it, and on this the outline of the figure is carefully traced with a pencil. This tracing is then laid on a sheet of brown paper, and with a sharp penknife the outline is cut through both papers; this gives us the two masks. The tracing-paper is then thrown away, as its only purpose was to enable an accurate mask to be obtained in the brown paper—that being too opaque for the outline of the picture to be seen through it. The background mask is then fitted on to the negative, and secured with gum or india-rubber solution. The edges are then trimmed off even with those of the negative, which is now ready for printing. When the negative is put into the frame it is pressed close into one angle, and secured there with a strip or two of gum paper. The tissue is then placed on the negative, care being taken that it, too, is pressed closely into the same angle of the frame, the edges of it being previously cut perfectly true to enable this to be done with accuracy. Now, it is clear that, as the negative is fixed, if the tissue be carefully placed in the angle of the frame in the first instance, it can be removed and replaced again in the same position with the greatest certainty.

When the figure has been printed the frame is opened and the tissue removed. Then the figure mask is taken and adjusted on the negative in the opening from which it was cut, and, as the paper is thick, this is easily accomplished. The back of the figure mask is now touched in several places with india-rubber solution. The tissue is then replaced on the now entirely covered-up negative and the frame closed, care being taken that the figure mask is not misplaced, and that the tissue is pressed close into the angle of the frame.

After resting for a quarter of an hour or so—or until it is judged that the rubber cement has dried—the frame is opened and the tissue removed, when the figure mask will be found firmly adherent to it and in accurate position. The background is now printed in, being shaded or toned as desired. When this is done, the mask pulled off the tissue, and any adherent india-rubber gently rubbed off with a clean finger, the print is then ready for development. The india-rubber, if carefully removed, will be found to have no injurious action whatever on the print.

Next week we shall describe the ingenious method adopted by M. Lambert in combination printing, as we witnessed it carried out at one of his demonstrations of the so-called "Lambertype process."

A WORD ABOUT STUDIO BUILDING.

We would direct attention to a most useful article under the above title, which appeared in our columns of the 4th instant, from the pen of Herr Emil Fuchs. It is pregnant with suggestions of a practical nature, and may be read with advantage by any of our readers interested in, or contemplating the construction of, studios. Only those who number among their acquaintances a few possessors of glass roofs have any conception of the constant annoyances that are liable to crop up so continually in connection with one phase or another of the roof and lights. These annoyances are by no means of a sentimental kind, as witness many a spoiled carpet or piece of furniture, not to speak of clients' dresses, or, still worse, of a picture brought to be copied and altered, but not "improved" by the falling of a drop or two of dirty water from the roof upon the features of the portrait. Then, again, there is the usual round of dirt and discomfort inseparably attendant upon the advent of the plumber and painter.

That such difficulties should exist is by no means a necessity of the case, and possibly Herr Fuchs points out the true cause of their presence when he speaks of the photographer knowing what he wants and the architect not taking the trouble to understand. The instructions and directions of the former, he says, do not combine easily with the manner of execution customary in the building trade, and they are rather allowed to fall to the ground, since "an experienced builder is sure to know best." When he assures one that this or that drawback can be removed in some other way, the photographer is overruled, is fain to be persuaded that the builder's way is the right one, and the result is, and remains, the usual one—mistakes are made, and only observed when too late. This is too much like the experience of all who have to do with specialist workers to be anything but true, and quite bears out what we have ourselves been told.

With regard to the actual details: some practical hints are given which are very valuable, but we would dissent from the writer's contention about the width of the squares of glass. He recommends, when plate glass is not employed, that the width of the pane should not much exceed twenty centimetres—that is, about eight inches. Now, this would be all very well for a greenhouse, but for a studio window would look too petty to find favour with English photographers, who prefer bold squares of large size—some studios, indeed, being glazed with plate glass. Apart from the appearance or effect of large *versus* small squares, there is another consideration that must not be lost sight of, and it is one which from a sitter's point of view we—having been much photographed —can speak from experience. We refer to the effect produced upon the eye by the window astragals. When they are at all numerous they are, even in a brief sitting, excessively fatiguing or irritating to the eye, even when the head is turned well away towards the shaded side of the room.

Some time ago we gave our readers a hint, imparted to us by an old glazier during an experience with greenhouse work, but naturally equally applicable to studio building. It was that, preparatory to putting the panes of glass into their place in the roof, they should have a preliminary treatment by giving a narrow margin of paint on each side, along the edges that were to rest in the frame or astragals. By this means the putty, to use the expression of the trade, will "grow to" the glass; in other words, adhere more firmly. Another hint may here be given, and that is, wherever ground glass is being employed in lieu of clear glass, it should first have a thin coating of "size" on the rough side. When this is done that disagreeable greasy effect caused by the oil of the paint spreading by capillary attraction, and which cannot be removed at first for fear of disturbing the setting of the putty, may be entirely avoided.

Herr Fuchs says he writes as a "glazier of twenty years' standing;" hence his words must be received with the more respect that they bear upon them the impress of thought. There is, however, a point raised in them so opposed to the common practice of most glaziers with whom we have had to do that we here refer to it with the hope that, as it is a very important question, some practised hand among our readers may give us the benefit of their actual experience upon these matters; for though theory guides, practice must decide. The writer says:—"It is of very special importance that the putty should be prepared with varnish and not with linseed oil, because the former dries slowly from without inwards, whereby an external skin is formed, which prevents any air from penetrating, and the putty always remains fatty. On the contrary, putty prepared with linseed oil puts on no skin, and is, therefore, very soon soaked off." This is opposed to our view of what happens, but there is putty *and* putty. When good oil is used and no water is mixed up with the mass to give weight, after the plan of the ingenious sophisticator of the period, we should imagine the putty would soon harden at the outside. Besides, it is often recommended by the authorities that this very skin-forming should be prevented, as being conducive to the production of cracks by the expansion and contraction following upon the heat from the sun's rays striking the roof; and receipts for making putty for the special purpose of roof or skylight glazing are to be found in which tallow is mixed in large proportion in order to render the putty pliable and cause it to remain so to a slight extent.

We conclude by drawing attention to an important and humane recommendation he makes, analogous to one which appeared in our pages nine or ten years ago. This is to provide the roof with some kind of permanent arrangement to aid the safety of the workmen who have to go upon it to paint or repair. When workmen pass over a slate roof they have no fear; if they stumble the slates form a safe support for their hands, and there is no danger of an accidental step plunging them through the roof. With glass, on the contrary, there is no foothold except the extemporised planks, which are difficult to make very secure, and no support but the sash-bars, when, if the body fall forward by any chance, the hands are thrown out to avoid a fall. Herr Fuchs recommends small pegs permanently let into the astragals to support any plank that may be required for the workman's use. The writer to whom we referred used—and we think it a still readier and better plan—pieces of angle-iron screwed at regular intervals into the astragals or bars.

In addition to this plan being advisable on the ground of humanity it evidently saves expense, as a platform can be much more readily and quickly arranged when workmen are needed. In addition to these pieces of angle-iron, the gentleman we speak of described also a platform he had constructed with the same object in view, so that in case of a stumble, which might otherwise result in a fatal accident, no harm could befal the workman. He described a wooden platform, more than a foot wide, at the eaves of the roof, further protected by a light iron fencing, hurdle fashion, secured to its place by strong iron staunchions bolted into the wall. Such precautions are advisable on all grounds, and we should like to hear of their becoming more common. There would, we are assured, be less delay and more comfort in getting workmen overhead to repair or put in order photographers' glass roofs.

We this week give a portrait of Mr. Leon Warnerke, being the first of series—which will appear, at short intervals—of individuals well known in connection with modern photographic progress. We trust that this method of familiarising our readers with the *personnel* of many of those whose names are well known to them will prove interesting.

Our next portrait will be that of Captain W. de W. Abney, R.E., F.R.S.

The "Traveller in Search of Sunshine" of the *Daily Telegraph* in saying that Naples "does not photograph well" only states his own experience, which probably, at the best, goes no further than to prove that Neapolitan or Italian photographers take but a minimum amount of trouble over their work, and leave difficult subjects to take care of themselves. A charming picture of the town and bay of Naples, given to us by Mr. Woodbury some few years ago, and which is now before us, affords the fullest refutation to the statement alluded to. A more difficult subject could scarcely be selected. A foreground of dense foliage in close proximity to the camera is backed up in the extreme distance by Vesuvius, with the whole sweep of the bay and town in bright sunshine intervening. Yet, from the light clouds in the sky and the faint line of smoke drifting away from the summit of the volcano, through the whole gamut of tints to the deepest shades of the foreground foliage, in every part of the picture there is detail, the *tout ensemble* being anything but confirmatory of the *Telegraph* correspondent's *dictum*. The picture is one of Mr. Woodbury's well-known Italian series, taken upon collodion emulsion plates.

Speaking of collodion emulsion: we could not help remarking a few days ago, when examining some negatives of this very series, that there is a beauty about a fine collodion emulsion negative which neither gelatine nor wet collodion will give. Why will not some of our experimentalists give us a dry collodion process as rapid as gelatine?

It was only the other day that the astounding news of the liquefaction of the "permanent" gases—oxygen and nitrogen—was given to the scientific world, yet, now, the fact has become so old a record that all novelty is gone from it; and the philosophers are calmly engaged in noting particulars of the mode in which liquid oxygen boils, and in endeavouring to ascertain its boiling point—that is, the temperature of ebullition of a liquid which bubbles and boils at a temperature far lower than any that has been met with by explorers who have been nearest the North Pole. M. M. S. Wroblewski has presented to the *Académie des Sciences*, of Paris, an account of his experiments in this direction, in which he states that—reserving details for a future communication—he may give one hundred and eighty-six degrees below zero (— 186° C.) as the first approximation to the temperature produced by the sudden release from pressure of liquefied oxygen. Nitrogen he solidified by the action of boiling oxygen. With regard to the latter liquid, he says:—"Indeed, the industrial production of liquid oxygen is, I may almost say, only a question of the material means at the disposal of the experimentalist." Still, notwithstanding all this, we cannot but fear that the time has not yet approached when we can order a bottle of oxygen and a dozen lantern slides to be sent home as a common matter of business.

It is stated that, during the earlier appearance of the wonderful coloured twilights which have evoked such interest during the last month or two, the light was put down in some places as due to the effect of a conflagration. At Poughkeepsie, on the Hudson, the fire engines were called out on the morning of November 27th last. We are still without information of any attempt to obtain a photograph by its light, or of the spectrum it would give.

Possibly it would meet with no more success than has followed attempts to photograph displays of the *aurora borealis*, with which it was at first confused, but with which, as we said long ago, it is not connected in any way. The report by Captain H. P. Dawson, of the circumpolar expedition to Fort Rae, states that it was found impossible to obtain photographs either of the *aurora* or of its spectrum. Surely this very impossibility of photographing what might be termed a really brilliant light may help to gain some knowledge of its cause. It was but a few weeks ago that we described a similar want of success following the efforts of a Norwegian investigator.

It could not have been very pleasant work, this photographing at Fort Rae; for, at the outset of the final stage of their journey, the party had an upset—provisions, instruments, and everything being submerged in the water through the storm staving in their boat and sinking it. The food was damaged, one barometer and one thermometer broken, the object-glass of the telescopes of most of the magnetic instruments were nearly opaque through the cementing having gone wrong, and, finally, not a single instrument was in working order through the case being full of water. When they were cleaned and set up the transit instrument was found not half strong enough to bear the necessary rough usage without risk of jarring it so as to upset its adjustments. We presume the authorities did not deem it necessary to send valuable and delicate instruments in water-tight packages to the North Pole. Probably they expected they would form their own casing of ice.

If the *aurora*, so far, has eluded the eye of the camera, the Liverpool Astronomical Society has scored another success in other directions in celestial photography. The Rev. T. E. Espin, writing under date of January 1st, states that they had succeeded the day before Christmas Day in photographing the Pons-Brook comet. "The exposure was fifty-three minutes, and the comet comes out on the plate as a circular haze without any trace of a tail. * * * A heavy dew was falling, and the lenses were badly covered." This latter circumstance may very possibly account for the hazy appearance of the image.

M. Trepiod also has been examining this comet, but with the spectroscope, and an account of his observations appear in the *Comptes Rendus* for the 31st ult. He found a tail two degrees in length, and, when examining the appearance of the comet's spectrum almost at the same time when Mr. Espin was photographing it, he found several bands which, strange to say, were practically identical with those of alcohol. When it is remembered that Captain Abney, at the meeting of the British Association for the Advancement of Science, in 1882, also found evidences of alcohol being distributed through space, one cannot avoid echoing the speech of the President of the Section, who asked if the total abstainers might like to make any remarks upon the discovery.

The paper by Mr. Hume Nisbet, read before the Edinburgh Photographic Society (a portion of which we print in abstract in another page), is said to have attracted a large number of the artists of Modern Athens to the meeting. A friend who was present informs us that "Mr. Nisbet is a 'free lance' who has been tilting at the Royal Scottish Academicians, and whose weapon was poisoned or rather barbed with truth, which made his attacks all the more cruelly telling. The R.S.A's present maintained a sullen but discreet silence. Mr. Nisbet illustrated his remarks by rapid sketches in charcoal, executed with marvellous rapidity and great ability, using either hand at once, producing quite a sensation by his startling effects by apparently simple means."

Who says that the pulpit is now opposed to science? We gladly place on record a sentence from a sermon by the Rev. J. E. Manning, M.A., of Swansea, just published, entitled *In Memoriam: Sir William Siemens*:—"Let me beg of you to notice," says Mr. Manning, "that the spread of science has had the same humanising effect as pure religion. If there is one thing clear in the present day it is that science, with the industrial arts and the industrial spirit it has called into existence, is the great prime mover in our modern civilisation, bringing the nations into even nearer and more friendly relations, and spreading one common interest over many lands."

Dr. Gore recently read a paper recording a number of instances in which various solutions of metals were reduced to the metallic state by contact with gases. Among the most beautiful films so obtained he stated was that of chloride of gold. He suggests that the films of metal thus produced might prove of service in some optical and other physical investigations.

The House of Peers has held few, if any, more worthy representatives of science than the present Lord Rayleigh, and we need not say that photography has not been left unstudied by him. He has lately printed, for private circulation, a pamphlet containing several of his most valuable optical papers, including those on the manufacture, reproduction by photography, and theory of diffraction gratings.

A new electrical incandescence lamp has been introduced by Mr. J. C. Fuller, of Finsbury Pavement, for philosophical purposes. For occasional dark-room work, photomicrography, or any similar class of experimenting, it may form a most useful aid, as we learn that it is merely a zinc and carbon battery excited by a solution of bichromate, one excitation causing the light to last thirty hours, and the cost being only about threepence for each charge.

Most of our readers have heard of diatoms—small objects upon the investigation of which some philosophers spend nearly a lifetime, while microscopes of vast power are constructed almost for the sole purpose of examining them. Before the Royal Microscopical Society last month several of Mr. W. H. Walmsley's photographs of these structures were shown and admired. A paper upon the cell walls of these diatoms, by Dr. J. H. Flögel, was read and illustrated by many photographs of the subjects of his communication. These are naturally very minute; yet we read that as many as one hundred and seventy-four transverse sections were made from a single diatom! This feat (which is something like cutting off the extreme point of a needle and shaving into a hundred or two slices) displays an amount of skill and patience marvellous to contemplate.

THE LATE MR. J. H. DALLMEYER, F.R.A.S.

It was our painful duty, last week, to briefly announce the death of Mr. Dallmeyer. We now supplement that announcement by a few particulars of the career of this eminent photographic optician.

For a considerable period Mr. Dallmeyer's health, impaired by a too close attention to business, was such as to lead him to seek for recuperation by taking long sea voyages and making visits to other and distant climes. About a month since, when we last made inquiry relative to his health, we were informed that the accounts just previously received were of a most cheerful nature. On the morning of Friday week, however, the obituaries of the London morning papers gave notice of his death on the 30th of December, when off the coast of New Zealand, at the comparatively early age of fifty-three.

The influence exercised upon photography by his writings, and especially by the excellence of his lenses, has been of a marked character, and his name has become familiar in this connection throughout the world wherever photography is known or practised. Born and educated in Prussia, he came to this country at an early period of his life and entered the workshop of Mr. W. Hewitt, optician (a former pupil of Mr. Andrew Ross), who with the various *employés* soon afterwards became again transferred to the larger business factory of Mr. Andrew Ross, optician, under whose tuition Mr. Dallmeyer acquired his knowledge of optics, eventually becoming that gentleman's son-in-law.

At the death of the senior Ross, in September, 1859, Mr. Dallmeyer entered into business for himself, that of Mr. Andrew Ross being carried on by his son, Mr. Thomas Ross, and now known as that of Ross and Co. In his new sphere Mr. Dallmeyer devoted himself mainly to the manufacture of photographic lenses, although telescopes also received a considerable share of his attention.

The first appearance of Mr. Dallmeyer before the photographic public was at the meeting of the Photographic Society, in June, 1860, where he read a paper on *The Nature of Distortion as Produced by the Present Forms of View Lenses, and on a Lens or Combination of Lenses Free from this Defect.* Shortly after this Mr. Dallmeyer introduced his modification of the triple achromatic lens, which proved very useful in architectural photography, copying, and, indeed, for every purpose where entire freedom from distortion was required. Still later he modified the construction of this combination by increasing the diameter of the central concave lens so as to render it suitable for groups.

We may here observe that ever since Mr. Dallmeyer commenced business the excellence of his portrait lenses has been so thoroughly recognised as to have led him to bring out several series of them—all, with one exception, constructed on the same principle (that of Petzval), but differing as regards relative apertures and focus, so as to secure varying degrees of rapidity and covering power. The exception to which we here refer is that form of portrait objective in which the relative positions of the flint and crown in the posterior combination are reversed, so as to render it possible, by slightly unscrewing them, to introduce spherical aberration at will, and thus produce definition of a lower order.

The wide angle and rapid rectilinear group of lenses introduced by Mr. Dallmeyer are well known. With regard to the latter a considerable amount of discussion of a slightly energetic description arose, some years ago, relative to the respective claims for priority of its introduction as between Steinheil and Dallmeyer.

The single wide-angle lens, patented in 1864, by Mr. Dallmeyer, is one of great excellence. It consists of two crowns and one flint cemented together, the external form of the complete lens being a meniscus of rather deeper curvature than that commonly adopted previously. The latest patent obtained by Mr. Dallmeyer was for a lantern condenser formed by the union of two lenses, one of these being a plano-convex, the other a double convex, one surface of which was so nearly flat as to lead to its being supposed to be so by an inattentive observer. This side is placed next to the picture.

The deceased gentleman was a member of the Council of the Photographic Society of Great Britain at the time of his demise, and was for some time on the Council of the Royal Astronomical Society. He wore the Cross of the Legion of Honour and the Russian Order of St. Stanislaus, conferred upon him in recognition of his services to optical science. Medals were awarded to him at the following exhibitions for the excellence of his work:—London, 1862 (2); Dublin, 1865; Berlin, 1865; Paris, 1867 (gold and silver); Philadelphia, 1876 (highest award); Paris, 1878 (two gold medals and the Cross of the Legion of Honour). We need scarcely add that his death is lamented by a large circle of friends.

During the past few years the late Mr. Dallmeyer has taken no active part in the direction of the business, but had confided it to his son, Mr. T. Ross Dallmeyer; and, as a matter of course, it will be carried on, as hitherto, under his active management.

THE MERCURY DEVELOPER.—THE SENSITOMETER.

It is little wonder that when a new formula for development is given, and when we are told that the use of it will result in the possibility of reducing our exposures to one-fifth of what we have been accustomed to, there is some excitement in photographic circles, and that the matter is talked of at the meetings of associations. Yet I have seen no description at all of any definite experiments on Mr. H. J. Newton's mercury developer, although I have looked anxiously for such. In the absence of them I commenced a series myself and shall give the results, hoping they may be of some use. Lest it turn out (as I hope it may) that the only *very* partial success I have met with is due to my having received a "foolish version" of the formula, I describe the experiments.

I dissolved thirty grains of corrosive sublimate in four ounces of water, and at the same time ninety grains of iodide of potassium in one ounce of water. The latter solution was slowly added to the former, when a red precipitate of iodide of mercury was formed, which was quickly redissolved when the whole of the iodide of potassium had been added. I then made up the ordinary soda developer. This I did because it is only fair when a new formula is brought out to give it at least one trial keeping strictly to the quantities mentioned. I may remark, however, that a set of experiments made some time ago, with washing soda and other alkalies, persuaded me that none of those tried gave better results than did ammonia, and that washing soda gave results considerably inferior.

The formula then used was as follows:—

Washing soda (dried)........................	25 grains.
Sulphite of soda	4 „
Pyro...	2 „
Water (up to)	1 ounce.

A large plate was cut into a number of small pieces, so that there might be no chance of differences of sensitiveness. A slow, but very clear, plate was selected, as by its use there was less likelihood of a disturbance in the sensitometer readings from the action of extraneous light.

The small pieces of plate were each exposed under Warnerke's sensitometer screen. The exposure was not made by the phosphorescent table, but to a paraffine lamp, as the object was not to ascertain the sensitiveness of the plates, but merely the comparative results of different developers. As the exposures were pretty long (20 seconds), and were made one immediately after another, there was little chance of variation in the light.

Two of the plates were placed in a developing dish, and the soda developer was poured over them. Development was continued for about five minutes, long before the end of which period all action appeared to have ceased. One plate was now removed to the washing water, and into the developing cup were dropped for each ounce of developer three minims of the iodide of mercury solution. The developer was poured into the cup, then returned to the dish. There was almost immediately perceived a slight further action of the developer. After this further action had ceased the second plate was placed beside the first. On comparing the two the second showed two figures more of the sensitometer than the first, and, on fixing both, the last figures of the mercury-developed plate appeared slightly more vigorous than those of the others. Had I got the same result in developing two different kinds of plates with the same developer I should have pronounced the one about double as sensitive as the other.

I now proceeded to develope a plate with my ordinary ammonia developer, which, for the particular plates I was using, consisted of—

Ammonia	3 minims.
Bromide..	1 grain.
Pyro.	$1\frac{1}{2}$ „
Water (up to)	1 ounce.

I got a result not to be distinguished from that got by the soda and mercury developer.

I now tried the result of adding the mercury solution to the ammonia developer. I used the formula just given, but with an addition of four grains of sulphite of soda. Two plates were, as in the first experiment, developed in this. When all action had ceased one was removed and placed in water. The mercury solution was then added to the developer as before, when it appeared that a *very* slight further action took place. On examining the two plates afterwards there was found to be an advantage of one figure in the case of the mercury-developed plate.

One further experiment was tried. The object was to discover the result of *forcing* both with ammonia and with the mercury solution, and to find by which means the highest figure could be got. A plate was developed first in the ordinary ammonia developer, ammonia being added little by little till slight fog resulted. The same was then done with another plate, except that mercury iodide was added in small portions till slight fog became visible. It did so when about seven or eight minims of the solution had been added to each ounce of developer. The two results are not to be distinguished one from the other.

The conclusion to be arrived at from these experiments is that the mercury developer shows over the ordinary ammonia developer an advantage which is at the best so small that it is not worth taking note of. Certainly, for my own part, I should think so doubtful an advantage was dearly purchased by the introduction of a new complication which is not our method of development.

I have read the article by Mr. Henry J. Newton in the December number of the *Photographic Times*, and found, after his description of the developer described above, the two following statements, which appear to me very extraordinary:—"A fifty-grain solution of iodide of sodium used in the same way acts as a good accelerator." "A thirty-grain solution of iodine in alcohol, to which forty grains of pyrogallic acid are added, makes a good stock solution for accelerating development used the same as the other."

I have found all soluble iodides that I have tried to be restrainers in almost the same way that a soluble bromide is. Certainly iodine solution is a powerful restrainer.

Mention of the use of the sensitometer in the above experiments leads up to another matter on which I would say a few words, even at

LEON WARNERKE.

the risk of repeating what has already been said by Mr. W. E. Debenham and myself. What I wish to repeat is this:—*The indications of a sensitometer whose action depends on showing what is the least amount of light which will produce a perceptible effect on a plate are not reliable, unless we can be certain that the plate has received* NO *exposure to actinic light before development except through the sensitometer.* My reason for bringing up this matter again is that it was discussed at the last meeting of the Photographic Society of Great Britain, and that so acute an observer as Mr. Spurge failed to perceive the truth of the matter. I quote, from the report of the meeting referred to, the remarks of Mr. Debenham and the reply of Mr. Spurge:—

"The radical vice of all sensitometers was that they were read by observing the last of a series of tints which indicated merely what was the minimum amount of light which would affect a plate; but a plate might be made to render such a tint by other means than such as would render it rapid in the camera, especially if it had been exposed to extraneous light."

"Mr. Spurge, in reply, said that if the effect of pre-exposing a plate were to make it give a higher sensitometer number, it would also be to make it give a corresponding result of greater sensitiveness in the camera."

I think I can easily show that Mr. Debenham is right and Mr. Spurge wrong in this matter. Let us suppose a certain plate, which is being tested under a sensitometer—either Warnerke's or Spurge's or any other. We will suppose that the plate has had no pre-exposure to light. A certain figure appears on the last which is seen on the developed plate. What is now indicated is this:—The amount of light producing this figure is the least which will make any visible impression on the plate. Such amount of light reaching the plate at any time before development will produce a visible effect. No less amount will. We will suppose that the amount of light required is ten units, that being the amount which reaches the plate through the last tint or hole of the sensitometer which gave an impression. Now let us suppose that before the sensitometer was brought into requisition at all we had given the plate an exposure so that it received nine units of light all over: no appreciable effect would have been produced, as it requires ten units in all to do so. But the plate is then in such a condition that *one* additional unit will produce an appreciable effect, and the figure of the sensitometer which corresponds to one unit of light will now be visible, in place of, as before, that which corresponded to ten units of light. The plate will appear ten times more rapid than it did before it received the general exposure. But does Mr. Spurge imagine that it will be ten times more rapid in the camera on account of the pre-exposure? Certainly it will not. There may, for certain subjects, be a *very slight* advantage; but probably not, at the best, more than fifty per cent.

It may be asked—If the sensitometer be liable to give such grave mis-indications, of what use is it? I would reply that, except where we know the particulars of the manufacture of an emulsion and of the coating and subsequent treatment of the plates covered with it, the sensitometer is of *no* use as a precise measure of sensitiveness. It is useful, notwithstanding, as a practical guide whereby to form an approximate estimation. Such estimation, however, is not to be made by reading the last figure only, but by taking into consideration the general appearance of the image after fixing, and especially by noticing, as suggested by Mr. Debenham, what is the highest figure which shows any marked advance of density as compared with the next one higher.

Although the sensitometer does not by the reading of the last figure only give reliable results when comparing different plates, it gives perfectly reliable results when comparing different developers on the same batch of plates, as here any disturbance which may have crept in from pre-exposure in the case of one plate will show itself equally in all. W. K. Burton.

LEON WARNERKE.

Mr. Leon Warnerke, the subject of our illustration, is by nationality a Hungarian, though long residence in this country and his intimate connection with a large circle of English friends have in a great measure Anglicised him. A civil engineer by profession, Mr. Warnerke settled in England some years ago, when his tastes led him to adopt photography as a recreation; but, in the course of many years' devotion to the art, photography has been the gainer by many practical contributions made by him in connection with its progress.

Mr. Warnerke first appeared prominently before the photographic public in 1875, when, at a meeting of the South London Photographic Society, he read a communication on *Paper v. Glass*, and exhibited and described his "roller slide" and sensitive collodion tissue. In the same year he contributed to our columns articles on the proposed use of methylal as an accelerator in development. In the following year, before the Parent Society, he read a paper entitled *Investigations in Collodion Emulsions*, in which were embodied the results of a careful series of experiments on the relative values of different salts for emulsion purposes. Since that time Mr. Warnerke has been a constant contributor of papers to various photographic societies in this country and on the continent, much of his time during the past few years having been spent abroad.

The introduction of the Warnerke actinometer, based upon the employment of a phosphorescent tablet upon which to record the impress of the light's action, will be fresh in the recollection of many of our readers; while the sensitometer which bears his name and which also utilises the phosphorescent principle is now the recognised standard of measurement in connection with dry plates. The establishment of the lens standards of the Photographic Society of Great Britain is also due to Mr. Warnerke's breaking ground in that direction, a committee having been appointed by the Society at his suggestion to consider the matter.

Mr. Warnerke was in 1877 awarded the prize offered by the Photographic Association of Belgium for the best dry process, and three years ago he received the progress medal of the Photographic Society of Great Britain, of which he is one of the most active members.

Though England is his permanent home, Mr. Warnerke is quite as well known in photographic circles in Russia, Belgium, Germany, and France, the greater portion of his time abroad being spent in St. Petersburg, where by his energy, in the first instance, a photographic society and a photographic journal were started some three or four years since.

Personally Mr. Warnerke is of the most sociable and genial disposition, and ever ready to assist, by his advice or otherwise, in any matters photographic; and few of the regular frequenters of the meetings of the metropolitan photographic societies, or of those who have enjoyed his hospitality, but have cause to be grateful for his kindly assistance in some photographic difficulty.

THE RENAISSANCE OF GOLD AND HYPOSULPHITE TONING.

It will not do to dogmatise on the conditions of permanence or fading as regards silver printing. Freedom from every trace of hyposulphite of soda is, with much justice, considered one of the indispensable conditions through which permanence is secured; and still, in face of this we, and others, are aware of prints from which the fixing agent has not been thus removed, yet which, after the lapse of a considerable period, are as good as when freshly made.

Another instance of this occurs in connection with a certain item in the experience of our predecessor, as described by him at the meeting of one of our metropolitan local societies. From this it appears that about fifteen years ago he received from Mr. W. M. Ayres, who is well known as one of the most experienced of London printers, several photographs produced by a system of toning which left nothing to be desired as regards beauty, but as respects the principle involved in the toning of which it might be possible to entertain inimical feelings. As, however, Mr. Ayres's experience embraced the extensive printing operations carried on in connection with the Great Exhibition of 1862, and as, further, he was well known to have for several years taken the leading position in the printing works of Mr. William England, he was prevailed upon by the then Editor of The British Journal Photographic Almanac to give to its numerous readers an account of the method of printing adopted in the production of certain prints which are now declared to have retained their pristine vigour and beauty. But the process by which they were produced would seem to have been apparently so heterodox as to have induced the Editor to attach a semi-apologetic foot-note to the effect that, whatever theoretical objections might be urged against the addition of gold to the hyposulphite of soda bath, the fact of its being recommended by a printer so experienced as Mr. Ayres should induce those who desired to emulate his work to give the method a careful and thorough trial.

As the Almanac, in which the details of the process in question by which these unfaded prints were produced, has been out of print for fourteen years, we here give a brief synopsis of it:—Albumenised paper prints having been executed on a sixty-grain silver bath are treated in the usual way up to immersion in the toning bath, which is composed of—

Chloride of gold	1 grain.
Acetate of soda	30 grains.
Water	8 ounces.

In this the prints are placed, but care is taken to remove them before the toning has been quite completed. They receive their full tone in the following manner:—

A fixing bath is made by a saturated solution of hyposulphite of soda, which is diluted with an equal bulk of water, and to this is added a solution of chloride of gold in the proportion of half-a-grain of the gold to each full sheet of paper. In this bath the prints acquire a considerable degree of richness. Washing in water follows this fixing and toning operation. In the event of any prints having suffered from over-printing they are removed from the others and kept damp until the day's fixing is done, after which they are immersed in a weak solution of iodine and iodide of potassium. In this way they become of a blue-colour, more or less deep according to the amount of reduction. They are then placed in the gold and hyposulphite bath, by which they are restored, the whites being rendered of great purity.

The foregoing is substantially the process by which these fine prints were produced. Where a caution is required, or a suspicion capable of being hinted at in the soundness of the system, lies not in its use when correctly carried out, but in its abuse in making the toning and fixing bath do more work than it is capable of doing, by which gold toning gives place to sulphur toning. This, however, is no argument against the adoption of the system described, but only against its misuse.

CAMERA LUCIDA.—PALETTA OBSCURA. A STUDY IN LIGHT AND SHADOW.

[Abstract of a communication to the Edinburgh Photographic Society.]

My subject—the union of painting and photography—is not so short as you or I might wish it to be, yet I have tried to make it as terse as a subject so crammed with incident and so exhaustless in matter could be made. If you will try to endure it to the end I trust you will not be disappointed.

Photographers, as far as I have seen of them, are a jealous-minded race. They do not think enough of their art or of themselves. They are too apt to think that the painters despise them, while in reality the painters of today hang on to them as a drunken husband is apt to hang on to his good-templar wife during this festive New Year season, or, to be more poetic in simile, as a half-drowned sailor will clutch on, teeth and nails, to the hard rock, which may have broken up his rotten old boat, but now keeps him alive in the middle of the surf.

The painters of today have become realists, and photography is realism or nothing. A photographer, to be able to produce a good picture, must be a true painter in the highest sense of the word; so a painter ought to know the right qualities about a good photograph, whether he knows the mixing of the chemicals or length of exposure, or process of focussing, &c., or not, although to be able to compete, the tricks of the trade have to be learned. Witness Napoleon Sarony, Mora,* and such men, with their fancy dodges and splendid effects, and Seavey with his unapproachable backgrounds.

Thus my title is almost superfluous, for painting and photography, requiring the same direction of talent, are already united; only it may be of a little service to hear a painter avow the marriage publicly which is so constantly being consummated on the quiet.

It is in your work, as in ours, the doom to be often annoyed with talented triflers who dip a finger into all the sciences, and are for ever ready to dispute the point with the originators—buyers of brains, who imagine that their cash gives them full liberty to find all sorts of faults, or suggest improvements upon the worker's designs; who will not buy unless their idiotic improvements are executed to the last letter, and who afterwards lay the whole blame of the spoiling of the pie upon the baker when the guests condemn.

Having a direct object in view, I need not trouble you about chemicals or lenses, aurora lights, or secrets that you all now know much better than I, but will come direct to what is of vital interest to us both in our wedded state, viz., the seeking how we may put as much of the soul of Nature, with her innate force and feeling of motion, into our pictures as possible; the men, modern and ancient, who may best aid us by the examples and teachings they have left as a legacy to us; a quiet consideration of what they really have done for us; a right straight look at the men themselves, unbiassed by veneration or prejudice, with a consideration as to how much we have taken advantage of the legacies left to us.

The first aim of our investigation is, therefore, the exact imitation of Nature; that is, the outward form and appearances of Nature—the body, in fact, of that mystic Deity whom all men worship, no matter what is the dogma, whether they have a creed or whether they be creedless. Secondly, the feeling, sentiment, or sensations of Nature—how her appearance touches us, as we look upon her in the wealth and loveliness of her colouring, also how we may keep that sentiment alive in our light and shade. Here the painter, with his colours, gets a better hand and a long start ahead of the photographer, engraver, and etcher; and it is here that if those workers in light and shade can keep the sentiment as well as the painter in colours, they gain a double and richer triumph—the triumph of a racer who has been heavily and unfairly handicapped at the beginning of the race. Thirdly, the motions, actions, passages, expressions, and impressions of Nature. There, both in photographer and painter, the man himself is brought out, whether he be a trained mechanic or a born genius. Lastly, the perfect image, the whole innate force, which is the spirit and soul of that matchless creation toward which we must all constantly turn (as the sunflower turns or the daisy opens to the glance of day) for the light and life of our artistic beings.

Let us drop the weak word "artist" out of our consideration altogether. Personally I abhor it as denoting nigger minstrel, sword-swallower, or that undefinable member of society who plays with single foils and sable hairs inside a studio, enriched with Turkey ruggery, old armour, and marble busts. Let us, who are workers, be plain painters and photographers, never heeding the comforts of our surroundings, having only to do with objects as accessories to our work, thinking only upon the *utility* of every knickknack we may have, aiming only at the result without considering the trouble or the inconvenience to the animal who is bringing it all about, every conception or experiment being an undiscovered country which we mean to find all out and make our own—Stanleys or Thompsens with our Africas; Pizzaros conquering and annexing our Mexicos; plain, hard-working, earnest painters and photographers; brothers in one grand service—Art.

I think, at the present day, painters recognise this fraternal stand even more than photographers give them credit for doing; they know how much they are indebted to the camera for making matters lucid which were before obscure. Witness the galloping horses done by instantaneous processes, the shape of waves in full action, the rushing of waterfalls, and the contortions of muscles in moments of great excitement. How many of the old masters knew what a horse at full speed was like? and what eye-openers to battle painters those photographs have been! None of the sea painters were able to draw a wave in all its subtleties and froth accessories as painters nowadays may do if they study the imprint of a flying second; we may also have clouds in their strata, as they actually are, with shadows perfect in those artistic studies coming, like the institution of Christmas cards, more and more into vogue every year that we live. And painters do use them constantly, whether they admit the fact or, induced by a false pride, pretend that they do not. I see in every exhibition glaring evidences of hay carts and field horses, yachts and ships of all degrees, blankly copied, with hardly any disguise, from the photographic studies suspended in the shop windows.

Clear photographic studies, faithfully drawn out, and in the painting knocked about a little, sometimes not so true as the original to Nature, blurred and mystified into that obscurity which does for feeling with the crowd, the most original bit of painting being the man's signature who sells it, that strictly being his own, and not the copyright of either the photographer or the horse. And why not? Clouds will not wait on our pencils and palettes being set; horses will not stand until we draw out a faithful enough study of their forms, nor ships pause until we get in all the rigging. The winds are against it, and the waves. The hours flying along and tearing down the sun-shadows before we have fixed one line of them on our paper or canvas join in the protest, jeering at our deliberation, and mocking us as slow coaches in these steam engine days, we trying to crawl on six miles an hour, and dreaming that we can enter into competition with the mile-a-minute express.

The pride which keeps the artist silent, or makes him deny the charge of photo-borrowing, is an utterly false pride, and the sooner it is knocked out of sight the better for all parties. Why should we not correct our sketches—done for the sake of the colour and feeling, and not for the form—from faithful photographs? It does not hinder us from being original in the after-treatment, although it may save us much time in the elaboration of sketch-details. Why not save our precious time for something so much more worthy of it—the picture?*

Hitherto I have wanted so much to be original that out of conscientious scruples I would not use the photographic studies which some of my friends have sent me. I looked upon them longingly, and put them out of sight reluctantly, and so went down to seaboards and meadows, catching rheumatics and toothache, and wasting hours upon hours, and many valuable sheets of Whatman's hand-made paper, trying to draw out all the rigging of ships, and the shapes of cows, losing the effect often in my endeavours to get the manipulation, and in reality not getting a hundredth part of what I might have got with half an hour's rapid dashing on of colour effects, and a moment's focussing. At

* Three of the photographs shown at the meeting were by Sarony and Mora, kindly lent by Mr. J. L. Cox, representative of the firm of G. Mason and Co.

* Only not to the encouragement of lazy habits. At times (for the sake of practice), a painter ought to draw the most minute point-detail with the pencil, as a singer practises his scales, otherwise for the object the photograph is most to be relied upon for truth in all, *except perspective.*

present I know little or nothing about the art of photography, but I intend to make it my duty to learn a little more—enough to be able to sight a picture correctly, take and develope a dry plate, and afterwards fix a print; for I can perceive plainly that time is coming on with rapid strides to the point when, along with his present utensils of colour-boxes and sketching block, the painter will require to carry his camera and stand, box of dry plates, and head covering.

And how proper it is that it should be so a little experience will prove to every one. An old castle or abbey, or the view of a town, or even the markings upon the trees would take us days to outline—the buildings of the town, the fretwork about the abbey and castle, or knots and gnarling of the woodland, and even then it would be incomplete. To illustrate my meaning: look at even the most careful outline pencil drawings of Turner—one of the most delicate of outline draughtsmen, *when he liked*—or the scrupulous and untiring delicacy of his admirer, Professor John Ruskin, with his pencil, and compare those efforts with the lines about even the most commonplace photograph of a building or tree-trunk, and I need say no more on that point. The painter has lost the half and distorted the rest; and although the drawing may appear more attractive at first sight, the photograph will be the best, for it embodies the first grand principle of a painter's training—faithful imitation of the object which he desires to represent.

Photographers are apt to labour under the mistaken notion that we do not recognise this plain fact of artistic necessity; but we do, and if we do not have the manliness to own it that is our cowardice and not our blindness.

Be content, therefore, when you go into exhibitions and see the misty result of your photographic studies in the realism of to-day hanging all round, that this is recognition enough of the obligations palette owes to camera. HUME NISBET.

(To be continued in our next.)

SHEFFIELD PHOTOGRAPHIC SOCIETY'S EXHIBITION.

OUR correspondent, in his notice of the recent exhibition, did a slight injustice to our Liverpool friends, for which we now desire to make amends.

The Liverpool Amateur Photographic Association sent a large number of exhibits to the Cutler's Hall, and their work was greatly admired and appreciated. The whole of the competition pictures for 1883 were displayed. Mr. R. Crowe showed a fine collection of prints, mainly of instantaneous pictures in the streets of Liverpool. The Rev. H. J. Palmer gave a lantern lecture on the glaciers of Switzerland to a crowded and appreciative audience, and on the walls were displayed a considerable number of his pictures abroad. Mr. J. A. Forrest showed some excellent specimens of his work in North Wales; and Messrs. Earp, Pierce, J. W. Kirby, Twigge, and Tyrer, sent fine specimens of their photographic skill.

Among the most interesting of the exhibits were six pictures by Mr. Craddock from calotype negatives, taken in 1851, and exhibited in the Great Exhibition of that year. Although toned in the old way—in a hypo. and gold bath—no trace of fading is manifest; and the sparkle and vigour of these prints testify to the value of the now-discarded paper process.

PRINTING.

[A communication to the London and Provincial Photographic Association.]

THE subject of this evening's lecturette or paper, whichever you prefer to call it, has been entitled *Printing*. The vastness of this subject is, however, far beyond my capabilities, since we find it dating back as an art to a very remote period. My remarks will, therefore, be confined to that kind of printing adopted by photographers, and known as silver printing on albumenised paper; or what might with truth be designated "the fugitive photographic printing process."

I do not wish to occupy your time this evening with a lengthy description of all the various methods of printing, photographic or otherwise; neither shall I reiterate all the discoveries which led up to their elaboration, as I have little doubt but that our worthy curator, who was the instigator of this effort of mine, will not rest contented until he has made you acquainted with the secret workings of all and every process based on photographic research. Unfortunately for me there are no secrets attached to this subject which are not known to you all, unless it be that the ordinary silver print is not the most imperishable *souvenir* of photographic art one can possess.

Example 1.—Here are some samples which speak for themselves. These were all printed on the 19th May last. The faded ones have been exposed in a damp atmosphere, namely, a cellar. Those prints which have not faded have been kept under the ordinary conditions of the atmosphere. You will notice the extraordinary influence of damp on these prints.

The subject, then, we have to deal with to-night is the means employed to obtain positive images on a suitably-prepared surface of silver chloride, incorporated in albumen, by the direct action of light; and, if you will allow me, I will deal with this matter in successive steps.

If we expose ordinary white paper to the sunlight no change is seen to take place; neither should we notice much difference if we soaked a piece of pure Swedish filtering-paper in a solution of pure nitrate of silver, dried it, and exposed it to light; but if we were to coat the Swedish paper with gelatine, arrowroot, or some similar organic substance previous to silvering it, we should find that the paper would readily darken in the light. From this we gather that an organic compound of silver is formed, which is more easily acted upon by light than a layer of the pure salt would be.

Example 2.—Here are some prints which have been produced on filtering-paper soaked in gelatine, and silvered in the ordinary manner.

Chloride of silver behaves in a somewhat similar manner to nitrate when exposed to light in the presence of organic matter, excepting that chloride of silver is more sensitive; for this reason, as a sensitising salt for making prints, it has long been the photographer's sheet anchor. If I may be allowed to speculate, I would say that chloride of silver will in all probability be the printing process of the future; not in combination with albumen, however, but a mixture of gelatine and collodion on a sulphate of barium surfaced paper. At no distant date I shall endeavour to show you some examples printed as I have indicated.

In this tube we have a solution of silver nitrate in water; you will notice it is quite transparent. I will add a few drops of hydrochloric acid, and immediately a copious flocculent precipitate of silver chloride is formed. If I wash some of this chloride of silver, and expose it to light, it readily darkens. The same also happens when a soluble chloride, such as common salt, is added.

Example 3.—I will take one of these tubes, containing silver chloride, and expose it to burning magnesium ribbon. You will notice it has darkened considerably.

For the purposes of printing, we find it more convenient to form our silver chloride in a very much finer state of division on the surfac we intend to act on as a base for the picture, and chemical decomposition is resorted to for the attainment of that end, but not quite in the same manner as I have just shown you. A given proportion of one or more of the soluble chloride salts is incorporated in the albumen coating given to the paper. When this salted albumenised paper is floated on a moderately strong solution of silver nitrate the soluble salt becomes changed, and an extremely finely-divided layer of silver chloride results, the coating of albumen being rendered insoluble, or coagulated by the silver nitrate,

In this tube I have some white of egg (albumen); upon the addition of a small quantity of this silver nitrate solution you will notice a white cloud formed. This is coagulated albumen.

Dilute silver solution does not coagulate albumen perfectly; for this reason stronger solutions are used than would otherwise be necessary. When weak solutions are used, portions of albumen will be dissolved, producing an effect called stripping, and may be recognised by a semi-opaque scum floating on the surface of the sensitising bath; also dull patches and streaks on the paper itself.

Here are some examples of albumenised paper which have been floated for the space of three minutes each on silver solutions of six grains, nine grains, and twelve grains per ounce respectively, fuming thirty minutes.

Example 4.—It will be noticed that the nine- and twelve-grain examples are very good, but those on six grains have very little albumen left. Nearly all the paper used by silver printers throughout the universe is manufactured in the south-east of France, or in Saxony, and is designated, according to the mill from which it issues, either Saxe, Rives, or Renat "New Rives." These papers are sent out sized, ready for albumenising, which latter operation is performed very extensively in this country and in Germany. Each albumeniser has his own pet formula, and some degree of secrecy is observed by them all. The formula here appended is a fair specimen, and yields excellent results. To every gallon of fresh albumen, free from yolk or germ, add the following :—

Ammonium chloride	$1\frac{1}{2}$ ounce.
Barium chloride	$\frac{1}{2}$,,
Glacial acetic acid	$\frac{1}{2}$,,
Soft water previously boiled	4 ounces.

When dissolved add gradually to the albumen, beating constantly until the whole is a froth; after twenty-four hours subsidence, the mixture may be strained through fine cambric, and is ready for use. Coating is performed by floating the smoothest side of the paper on the albumen bath for the space of thirty or forty seconds, according to the nature of the paper; the sheet is then dried on laths or rods at a temperature of about 90° F. In Germany the sheets are pinned up by two corners to dry. The coarseness of texture sometimes noticed in silver prints is due to the paper being coated on the wrong side. Drying at too high a temperature gives a brilliant surface, but causes blistering in the after process. Drying at too low a temperature causes dullness. The quantity of albumen required to coat a ream of paper weighing ten kilogrammes will be about two gallons. Various tints may be given to the paper by the addition of suitable liquid dyes mixed with the albumen. Albumenising and sensitising cannot at present be successfully performed at one operation; as far as experiments have been made all attempts to preserve the paper have failed and the results have not proved satisfactory. Sensitising, therefore, becomes a distinct operation.

I may fairly assume that many present indulge in the luxury of ready sensitised paper; still I have taken the liberty of introducing this subject as one of the stages necessary to obtain a result. Silver nitrate and sodium chloride, if permitted to attack each other in the presence of water, form, as everybody knows, silver chloride and sodium nitrate. In practice it is not necessary to deal with exact equivalent proportions, it being sufficient to ensure an excess of silver nitrate strong enough to prevent stripping, and not strong enough to produce bronzing of the shadows to any appreciable extent. It has been pointed out in "Text-Books," "Lessons," and other places, what happens when silver chloride is exposed to light, and, no doubt, you are all familiar with the reaction from a practical point of view. We will suppose we are using a paper salted as above mentioned, viz., a paper coated with six grains of soluble chloride per ounce of albumen. We should make up the sensitising bath at least five or six times that strength, say forty grains of silver nitrate per fluid ounce of water. Half a gallon of this solution would give us a bath on which half a quire of paper could be sensitised. It would then be necessary to replenish with more silver, as about 290 grains of silver nitrate would have been converted into chloride or absorbed in the paper. Other nitrates with silver are used by some printers, the principal being the nitrates of soda and potash. They are said to effect a saving of silver, but they are seldom used by practical printers. I have appended a formula which has worked well in my hands:—

Nitrate of potash	35 grains.
Nitrate of silver	30 ,,
Water	1 ounce.

The time required for floating on such a bath will be from six to eight minutes, and ammonia fuming will be found advantageous when good results are desired. There is really no distinct advantage gained by the addition of any other substance to the silver solution. In proof of this statement, I now show you untoned prints sensitised on the following:—

Nitrate of silver	10 grains.
Nitrate of potash	10 ,,
Sugar-candy	10 ,,
Water	1 ounce.

Also,

Nitrate of silver	5 grains.
Nitrate of potash	5 ,,
Sugar-candy	5 ,,
Water	1 ounce.

The results are very little, if any, better than the prints shown from a weak, plain silver bath.

Fuming, for some reason or other, is not looked upon with much favour in this country, but why I cannot say. My experience commenced in this city fully twenty years ago, and I have continually practised it both here and in America since that time. It has been said that the climate of America is of such a nature that fuming is necessary, but that here there is no advantage gained. This is simply nonsense. America is far too large a country to be placed in the category of any particular climate. She possesses climates of all sorts; and, as my experience of fuming extends over some thousands of miles, I hold that fuming is desirable in any climate.

When hydrate of ammonia is exposed to the atmosphere pungent fumes of the gas are given off. If these fumes be collected in a closed box, and sensitised paper is placed therein, the sensitiveness is considerably increased—in fact, nearly doubled—and the colour of the print becomes purple, or blue, according to the energy of the gas and the duration of its action. Among other advantages, fuming permits less concentrated silver solutions to be employed in sensitising. Less time is occupied in printing, also in toning, meaning economy in time and material, and mealiness is never seen. It is for this latter reason that pictures printed on fumed paper give such better results in copying than those pictures which are printed on unfumed paper.

W. M. Ashman.

MANUFACTURE AND TREATMENT OF PHOTOGRAPHIC PAPER.

This invention, which received provisional protection only, emanates from Charles Cros and Auguste Vergeraud, both of Paris.

It relates to the manufacture and treatment of photographic paper for the purpose of reproducing by the action of light the dark lines of designs drawn on transparent surfaces—such as tracing-paper, glass, and the like—or the images of flat objects that can be applied to the prepared paper. The paper can be prepared either during its manufacture by mingling with the pulp the sensitive materials, or these can be applied to the paper at some stage of its manufacture (when it can be moistened) or after its manufacture, whether the paper be sized or not. Thus, there may be added to the pulp which is to be converted into paper a sensitising solution of about 11 parts bichromate of potassa and 120 parts of dry glucose in 1,000 parts water, the quantity of the solution being such that the sensitising ingredients constitute an addition of about sixteen per cent. to the weight of the dry paper. For sized paper the proportion of sensitising material may be considerably less. Or, again, manufactured paper may be gelatinised in the usual way, impregnating it with a solution of about 10 parts bichromate of potassa, 100 parts dry glucose, and 25 parts gelatine, in 1,000 parts water. Paper thus prepared is particularly applicable for obtaining designs in organic colouring matters.

For developing, a solution of about ten parts nitrate of silver, twenty parts acetic acid, and fifty parts alcohol in 1,000 parts water, gives a ruddy colour, which after washing and drying in the light becomes dark brown. Hydrosulphuric acid gas, reducing salts of copper or iron, such as oxalates or ammoniaco-sulphites, carbonates of soda and potassa, may be then applied. By the action of the latter substances carbonate of silver is produced, which becomes blackened by exposure to light. Another developing solution consists of about twenty parts acetate of lead, twenty parts acetic acid, and fifty parts alcohol in 1,000 parts water. This gives a yellow, which is blackened by hydrosulphuric acid gas. Development in dark violet colour may be effected by applying a mixture of about twenty parts extract of logwood, fifty parts alcohol, and five parts carbonate of potassa, with 1,000 parts water, and then washing with water acidulated with oxalic acid to remove the colour from the ground. In all these operations alcoholic liquids are preferable to pure water, as they dissolve less the bichromate. For the glucose employed in the sensitising mixture dextrine, sugar, or gelatine may be substituted.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
January 22	Bolton Club	The Studio, Chancery-lane.
,, 23	Bristol Amateur	Studio, Portland-st., Kingsdown.
,, 23	Photographic Club	Anderton's Hotel, Fleet-street.
,, 24	London and Provincial	Mason's Hall, Basinghall-street.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of the above Association, held on Thursday, the 10th instant, the chair was occupied by Mr. W. K. Burton. This being one of the "lecturette" nights,

Mr. W. M. Ashman, as previously arranged, read his paper ***On Printing*** [see page 41], and illustrated it by experiments exhibiting the reaction of nitrate of silver with soluble chlorides and with albumen; and by handing round various specimens of silver printing produced with differing details of treatment.

At the conclusion of the lecture,

The Chairman, after thanking Mr. Ashman, said that he should be glad to hear if any member would say how sensitised paper could be prepared for keeping, so as to give results similar to those obtained with the commercial article. Mr. Ashman had said that he had made paper and kept it for a year, but that it required fuming before use. He (the Chairman) had tried all the formulæ that he had seen, but none of them gave results like that which was sold by the makers for the trade. It was remarkable how well the secret of the manufacture had been kept. These commercial papers did not require fuming, and were not acid to test paper.

Mr. W. E. Debenham inquired whether the Chairman had tried the method, which he had published some years since, of adding perchloric acid to the sensitising bath. Paper so prepared did not require fuming, and toned just as freely as those floated upon the ordinary bath. With respect to the practice of fuming paper with ammonia, which Mr. Ashman had remarked was so general in America but not in this country, perhaps one reason why it was not adopted (in London, at all events) was that after fuming the paper so soon discoloured, and with the winter light here sometimes the prints would not come off in one day or even in two.

The Chairman had not seen Mr. Debenham's formula, but would try it.

Mr. F. York prepared paper for keeping by floating it for three minutes upon the usual sixty-grain bath, and then for one minute upon a bath containing thirty grains of nitrate of silver and thirty grains of citric acid to the ounce. One grain more of citric acid was added to the bath for every sheet of paper floated. The nitrate of silver did not require to be replenished in the second bath. The paper so prepared would keep for a month, but he generally sensitised once a week. The paper did not require fuming, but as a final wash before toning the prints were immersed in a solution of common soda—about one ounce to the gallon.

Mr. PRESTWICH endorsed Mr. York's observations as to the advantage of a wash of soda before toning.

Mr. A. L. HENDERSON said that Mr. Ashman had spoken of his intention to prepare paper with gelatine and collodion for printing. He thought that there would be no gain in any way from the proceeding. The lecturer also had said that there was no advantage in the addition of nitrate of soda to the sensitising bath. He (Mr. Henderson) thought that there was a great advantage in doing so, and that if a five-grain plain solution of nitrate of silver were used to float upon the albumen would be dissolved, but if the solution were saturated with nitrate of potash this would not be the case. With a bath so saturated ten or fifteen grains of nitrate of silver to the ounce were quite enough. He had tried Mr. Debenham's plan of preparing sensitive paper long ago, and had found it wanting. Nothing had so much puzzled him as a method of preparing sensitised paper so that it would keep. He could prepare a paper as good as any in the market by the addition to the sensitive bath of a small quantity of oxalate of ammonia and honey. A trace of citric acid in the bath—one in five hundred—would also suffice to make paper keep. Mr. Debenham had said that fumed paper did not keep. His (Mr. Henderson's) experience was all the other way. Let any one wrap up some and try. Fumed paper kept better than paper that was not fumed; for what discolouration might come on would fix out, or nearly so.

Mr. J. TRAILL TAYLOR said that his experience of the keeping properties of paper after it had been fumed was not in harmony with that of Mr. Henderson. As to the relative permanence of prints produced by different methods: he would mention that some years ago Mr. W. M. Ayres had published, in one of the early volumes of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC, a formula which he (Mr. Taylor) could not at the time recommend, as it was a variety of the old method in which the gold and hypo. were used mixed. He had by him, however, some prints which were produced by that formula at that time, and they were now brilliant and beautiful.

Mr. Ayres showed some unmounted prints produced twenty-two years ago.

The CHAIRMAN remarked that they might have been produced yesterday.

In reply to a question,

Mr. AYRES attributed their permanency to a liberal use of gold. The fixing was performed in a solution of hyposulphite of soda, one in twenty, and the prints kept in it for fifteen minutes. The toning bath, which was what he still used, was composed only of chloride of gold and lime water, made the same day as used.

Mr. HENDEASON believed that the old method of mixed hypo. and gold gave the most permanent prints of all. As to the paper itself, he believed that it was not nearly so good as that which was made twenty years ago.

Mr. F. W. HART said that the great danger of fading was from the use of an old acid bath for fixing. He made a practice of having fixing and toning solutions and washing waters all in the proportion of a pint for thirty *carte* prints on each whole sheet of paper. The gold used was in the proportion of half-a-grain to the sheet, and the fixing solution one part of hypo. to ten of water. He did not allow the prints to remain all night in water; but, commencing at five in the afternoon, they were washed in many changes of water, then immersed in a dilute solution of hypochlorite of lime to eliminate the last trace of hypo., again washed, and dried. This occupied till about nine o'clock.

Mr. W. T. WILKINSON had used Mr. Blanchard's plan of preparing paper, by adding citric acid to the nitrate bath and redissolving precipitate with nitric acid for keeping, whilst he was in India. The paper did not require fuming except in very dry weather, and then it was necessary in order to get rich prints.

Mr. HENDERSON thought it a great pity that alkaline toning ever came in. The only advantage that he could see was that it cost less for gold than the older method. As it is he toned four sheets of paper with one grain of chloride of gold.

Mr. DEBENHAM said that, as some prints produced by both methods had stood very well—Mr. Ayres's lime-toned prints on the table being good examples of permanence by the alkaline plan, and some prints by both methods had faded very rapidly—they would do well to look out for some other cause of fading than the adoption of either of the plans. One cause that he thought very active was the decomposition of the sizing of the paper, or of the mounting material caused by damp or immersion in water. Let any ordinary photograph be stood in a pickle jar containing a little water at the bottom, covered over, and placed outside a window, and in a fortnight it would be found to have faded fearfully. Any print that would stand that treatment might be considered, as photographs go, permanent.

Mr. ASHMAN, in conclusion, said that sensitised paper kept with him for a twelvemonth. Fumed paper remained very well for a fortnight if kept from air in a box or frame. The padding of his frame was a sheet of red india-rubber. This was a good material in many ways; it equalised the pressure, and preserved the paper from air and moisture.

On the motion of the CHAIRMAN, seconded by Mr. DEBENHAM, a cordial vote of thanks was given to Mr. Ashman, who promised on a future occasion to continue the subject by going into the questions of toning and fixing, at which the present paper had stopped short.

Mr. HENDERSON showed some examples of negatives, one of which was developed by Mr. Newton's corrected formula for the addition of mercuric iodide to the sal. soda developing solution, consisting of the use, with each ounce of developer, of three minims of a mixture of thirty grains of bichloride of mercury and ninety grains of iodide of potassium in four ounces of water. He considered that there was a gain in exposure of two to one compared either with the ordinary sal. soda developer or that in general use with ammonia.

It was announced that at the second meeting, in February, Mr. F. W. Hart would give his "lecturette" on *Residues*, and that in March and April Mr. T. Bolas and Mr. W. E. Debenham would give theirs on the subjects respectively of *Photo-Block Printing* and *Lenses*; and the meeting concluded with a hearty vote of thanks to the Chairman.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE third meeting of the session was held at 18, George-street, on Monday, the 7th instant,—Mr. William Nielson, President, in the chair. The room was inconveniently crowded, between eighty and ninety members being present.

The minutes of the last meeting having been passed, the following were unanimously elected ordinary members:—Messrs. W. Adams, H. B. Melville, William Peek, William H. Muir, J. Clinton Nott, William Meikle, James Lessels, W. Cuthbertson, Andrew Paterson, and Miss Ann C. S. Calder.

Mr. H. H. PILLANS proposed:—That the Council be empowered to expend a sum, not exceeding £5 every year, in purchasing books towards forming a library for the Society; that the Council may suspend this payment any year they think that the funds of the Society do not warrant such expenditure; that the Council determine what books shall be purchased, where kept, and how made available to members.

In the discussion of this motion the President, Mr. J. Smart, R.S.A., Mr. J. M. Turnbull, Mr. J. B. Stewart, and Mr. Fraser took part. The latter gentleman suggested that the Secretary might communicate with other societies in Edinburgh to bring about united action for the securing of suitable rooms where various bodies might hold their stated meetings, with accommodation for books, apparatus, &c., and a permanent caretaker. There was a general expression of opinion that such premises were greatly needed in Edinburgh. Ultimately it was agreed, on the motion of Mr. J. Henderson, that the question of rooms, &c., be referred to the Council with full powers.

Mr. HUME NISBET then delivered a lecture entitled—*Camera-Lucida, Paletta Obscura, The Union of Painting and Photography*. [See page 40.] Mr. Nisbet illustrated his remarks by a number of photographs from various sources, and by rapid charcoal sketching. The lecture was listened to with marked attention, and the beautiful word-painting elicited frequent applause. At its conclusion,

The PRESIDENT said the Society was much obliged to Mr. Nisbet for his interesting and practical address, which was both instructive and suggestive. In some respects, however, he differed from what had been advanced. He was afraid that the painter who relied on photography would find that it tended to interfere with the freedom of his brush, and conduced to a mere hard rendering of details. Photography had its own province in black and white; but coloured canvas involved a different principle—the principle of selection. The details of nature were grand by their dimension; but if these were crowded into a small canvas they became paltry, not conveying a feeling of nature. The business of the painter was not to give a paltry imitation of nature, but to translate nature into art, by missing out non-essential details so as to enhance the leading features of the scene on which its character depended. In concluding he alluded to this mode of treatment in Turner's grand picture of *Loch Awe*.

Mr. J. G. TUNNY said the meeting could not separate without according to Mr. Nisbet a hearty vote of thanks for his most interesting and instructive lecture. There must be few, if any, in the audience who had not felt their souls stirred by the graphic word-pictures that had been presented. The perusal of the lecture, he hoped, would make every photographer proud of his art, and awake in each a stronger ambition to realise the ideal he had placed before him; and he hoped it would also have the effect of lessening the unconcealed prejudice that is sometimes evinced against the productions of the camera by those who use exclusively the palette and the brush.

Dr. THOMPSON seconded the motion, which was carried with applause.

Mr. J. M. TURNBULL exhibited an ether generator and Dickson's improved burner for the lantern.

Mr. J. CRIGHTON exhibited a large collection of photographs by Mr. Foster, of Coldstream. These were hung round the walls of the room, and were examined with great interest, Mr. Nisbet making use of many to illustrate his lecture.

A number of photographs by Messrs. Crighton, Matheson, Murray, and Dr. Sidey were distributed by ballot.

The attention of members was directed to the first "popular" meeting, to be held on Wednesday, the 23rd instant, and members were requested to send in their transparencies to the Curator or Secretary as soon as possible. None would be exhibited if received after the 19th instant.

After a hearty vote of thanks to Mr. Turnbull, Mr. Crighton, the contributors to the ballot, and the Chairman, the meeting adjourned, to meet again in 5, St. Andrew Square, on Wednesday, the 7th February.

PHOTOGRAPHIC SOCIETY OF IRELAND.

THE usual monthly meeting of this Society was held in the Royal College of Science, Stephen's Green, E., on Friday last, the 11th instant,—Mr. Greenwood Pim in the chair.

The minutes of the previous meeting having been read and confirmed, the following gentlemen were elected members:—Messrs. Joseph Dollard, William Rigby, J. C. King, and P. Crosthwaite.

Mr. ALEXANDER CONAN gave a most interesting account of a visit to the recent exhibition of the Photographic Society of Great Britain. He also passed round a number of copies of photographs which were there exhibited, some of Professor Donkin's Alpine views being particularly beautiful. In the discussion which followed,

Dr. PEARSALL thought that amateurs as well as professionals might learn a great deal from colour artists in the way of producing picturesque as well as really artistic pictures; for, as he remarked, often by shifting the camera a little to one side or the other and by using a little judgment in the choosing of the subject, very much better pictures would be produced than they were at present accustomed to see.

Mr. Watson exhibited Messrs. Atkinson's new camera and instantaneous shutter, kindly lent for the occasion.

The next meeting is intended to be held on Friday, the 8th February.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.

The annual meeting of the above Association was held in the College of Physical Science, Newcastle-on-Tyne, on Tuesday, the 8th instant,—Mr. James Downey in the chair.

The third annual report was read by the Secretary as follows:—

Annual Report.

Your Council have pleasure in offering to you the third annual report. The past year has been a busy and prosperous one.

Since the last report was issued, four members have resigned, and five names have been removed from the books.

The Society now numbers 81 members. Eleven gentlemen have joined during the year.

The ordinary monthly meetings have been well attended. Four outdoor meetings were held, and were very successful; Mr. Maling's kind offer of a medal contributing largely to this result.

Three practical demonstrations have been given, and two lantern demonstrations. These were highly appreciated.

The success of the Society's exhibition, held in the Central Exchange Art Gallery, was well assured—the list of contributors containing as it did the names of numerous well-known prize winners. The exhibition was highly spoken of by the local press and by the photographic journals.

The best thanks of the Association are due to the Council of the College of Physical Science for placing their rooms at our service; to the Rev. T. F. Hardwich, Messrs. Edgar Goold, Thomas M. Laws, J. B. Payne, J. Pike (two), Lyddell Sawyer (two), and A. A. Campbell Swinton for the contribution of papers; also to the President, Mr. R. Jobling, and Mr. George Bruce for acting as judges at the exhibition.

Your Council trust that a liberal supply of papers will be forthcoming at the ensuing meetings, and rely on your generous support and assistance.

J. Pike, Hon. Sec.

The Treasurer (Mr. P. M. Laws), en presenting the financial statement, said it was satisfactory, considering the severe strain there had been upon the funds, to be able to show a balance on the right side at all. Not only had the expenses incidental to the exhibition to be met, but the presentation prints for the preceding year had to be paid for. To defray the cost of the latter alone the balance from 1882 was reduced to less than five pounds. The entire cost of the exhibition was £31 1s. 5d., and when the sum realised by advertisements in the catalogue was deducted, the actual disbursement for the exhibition was £24 8s. 4d. As a set-off against these two items in the balance sheet, each member received, for 1882, a print nearly, if not quite, equal in value to his annual subscription, whilst for last year members received an exhibition ticket entitling them to a fortnight's free admission to the Art Gallery. The balance sheet shows an advance of eight subscriptions over last year, and three more were received after the accounts were audited. There were still, however, six subscriptions in arrears. All things considered, the Association was financially in a very satisfactory position, there being a small balance on the right side.

General Statement of Receipts and Expenditure, 1883.

Receipts.	£	s.	d.	Expenditure.	£	s.	d.

31st December, 1883.

Examined and found correct,
E. Schumann.

The reports were favourably criticised and unanimously passed.

Mr. J. P. Gibson proposed, in eulogistic terms, a vote of thanks to the Secretary and Treasurer.

After remarks by Mr. Sawyer and the Chairman the vote was carried with acclamation, as were also thanks to the President, the Auditor, and the Exhibition Sub-Committee.

The Chairman presented to the Association, on behalf of Colonel Sheppee, a handsome portfolio.

The Secretary was requested to convey the thanks of the Association to Col. Sheppee for his useful and much-wanted gift.

The scrutineers (Messrs. T. M. Laws, Ridley, and Gray) appointed to examine the voting papers reported the result of their investigation as appended:—*President:* Col. Sheppee.—*Vice-Presidents:* Prof. A. S. Herschel and Prof. P. Bedson.—*Hon. Treasurer:* Mr. P. M. Laws.—*Council:* Messrs. Auty, Dodds, Downey, Gibson, Goold, Galloway, Payne, Maling, Ridley, and Sawyer.—*Hon. Secretary:* Mr. J. Pike, 11, Grey Street, Newcastle.—*Auditor:* Mr. E. Schumann.

In accordance with notice given at the previous meeting the Hon. Secretary moved to alter rule 61 by making the subscription for ladies 5/- per annum, and said that his object was to increase the number of members, to assist the funds, and to make the Association more social in character. Of course such lady members would receive presentation prints and be on the same footing as other members, except with regard to holding office. The motion was, after some little discussion, passed.

The adjourned discussion on Mr. A. A. C. Swinton's paper, entitled *The Past, Present, and Future of Photography in Natural Colours*, read before the Association, December 11th, 1883, was opened by the Secretary, and was sustained with much animation by Mr. Gibson, Mr. Downey, Mr. Pae, Mr. Sawyer, Mr. Laws, Mr. Swinton, and other gentlemen. At the suggestion of Mr. J. P. Gibson the discussion was again adjourned, pending the result of some promised further experiment.

GLASGOW AND WEST OF SCOTLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

A meeting of this Association was held in the Religious Institution Rooms, on Tuesday, the 8th instant,—Mr. Hugh Reid, President, occupying the chair.

After the reading of the minutes the following new members were admitted:—Messrs. Ross, Wingate, Horsefield, Bannerman, Barr, Smillie, Percy, and McKenzie.

Mr W. Snell Anderson was called upon to give a demonstration of enlarging on argentine gelatine-bromide paper. He employed an optical lantern fitted with a double-wick lamp, and made two successful enlargements from half-plate negatives. The demonstration was watched with interest by a large number of members.

Mr. J. Parker was then asked to explain his sky-shade, which, he said, he had pleasure in doing on that occasion in order to call attention to an improvement that had been made on it by Mr. Skinner. The improvement consisted in replacing the brass collar fitting the hood of the lens by a strong rubber band, by which means the shade could be fixed to any size of lens. In reply to the President, he (Mr. Parker) said that the exposure, when using the shade, was about doubled.

The British Journal Photographic Almanac and *Year-Book*, presented by the respective Editors, were laid upon the table.

It was intimated that at the February meeting Mr. T. N. Armstrong would give a demonstration of transparency-printing and mounting on glass.

Votes of thanks having been awarded to Messrs. Anderson, Parker, and the editors of the annuals, the meeting was adjourned.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

The deferred annual meeting was held on Saturday, December 1st, at the Association Studio, Portland-street, Kingsdown,—Mr. T. Davey, Vice-President, in the chair. The previous meeting's minutes having been confirmed,

Mr. E. Brightman, the Treasurer, read the accounts and balance-sheet, which showed the Association to be in a healthy financial condition. The accounts were audited by Messrs. Boyden and Phillips.

Mr. H. A. Hood Daniel, the Honorary Secretary, stated that the next business was the election of officers.

Colonel Playfair suggested that it might save time to re-elect all the officers together; but as there seemed to be a feeling that it would be better to elect each officer separately,

Mr. J. Phillips said he felt much pleasure in proposing the name of Mr. T. Davey, one of their Vice-Presidents, as President for the ensuing year. He thought that it would be impossible to find one of their members who took more practical interest in the Association than Mr. Davey, who was almost always present to preside over their meetings, and as it was he who nearly always did preside he did not think they could do better than elect him as their official President.

Mr. Boyden said he had very much pleasure in seconding Mr. Phillips's proposition, which, on being put, was carried unanimously.

The Honorary Secretary stated that there were now two vacancies to fill, namely, the Vice-Presidents.

On the motion of Messrs. Boyden and Phillips, the Rev. W. J. Whiting was re-elected; and, on the motion of Messrs. Davey and Brightman, Colonel Playfair was elected to the other vice-chair.

Mr. Davey proposed the re-election of Mr. Edward Brightman as Treasurer, and he did not think a more satisfactory banker could be found; for, although the Association paid its way, as every respectable institution should, still there was of course sometimes a cash balance against the Treasurer, and the way in which Mr. Brightman bore it was most exemplary.

Colonel Playfair had much pleasure in seconding the proposition, and did not think the accounts and funds of the Association could be in better hands.—Carried *nem. con.*

The re-election of Mr. H. A. Hood Daniel as Honorary Secretary (if he would once more accept the duties, which were not light, but such as to occupy a great deal of time) was proposed by the President in eulogistic and complimentary terms, and, on being seconded by Colonel Playfair, was carried *nem. con.*

One of the existing vacancies in the Council was filled by the election of Mr. J. Phillips.

The meeting then formed itself into Committee and discussed the extensive arrangements requisite to be made for the successful carrying out of the International Photographic Exhibition, with regard to which the report given by the Honorary Secretary was of a very satisfactory nature, especially with reference to the number of foreign exhibits and the gentlemen who had kindly signified their willingness to act as jurors.

At the conclusion of the meeting the Honorary Secretary expressed a hope that every member who could would do his utmost to contribute a paper or communication of some sort during the session.

LEEDS PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting was held on Thursday, the 10th inst.,—when the newly-elected President, Professor Thorpe, F.R.S., presided. There was a very large attendance. In delivering his presidental address,

Dr. THORPE said:—It is unnecessary to take up your time by recalling the circumstances which have led to the formation, or rather to the reorganisation, of the Society. I would merely say that the extraordinary development of photography in these latter-day dry-plate days, and the extent to which the art is intelligently practised by scores of people in this district, to whom it is the chief delight and occupation of their leisure hours, have seemed to many of us to afford sufficient reasons for the establishment of a society on an independent basis and with an independent existence. We have every reason to believe that our confidence in the vitality of our Society is well founded. At present it numbers upwards of fifty members, and includes, I think, the names of most well-known amateurs in the district, and not a few of our leading professionals. Justice, however, should be done to those who have preceded us in our efforts to create a society here which has for its object the furtherance and development of the art. Leeds was amongst the earliest of the provincial towns in which the process of Daguerre gained a local habitation and a name, and to the late Mr. William Huggon must be given the credit of being the first resident portrait photographer in our town who taught and otherwise spread a knowledge of the process. More than thirty years ago a small band of enthusiastic workers centered round our Vice-President, Mr. J. W. Ramsden; but the Society seems to have become merged into a general scientific society, the photographic section of which lost its existence on the creation of the Photographic Society of London. Under the leadership of Mr. Washington Teasdale the Leeds Society was resuscitated about two years ago as a section of our local Natural History Society, and from this has sprung our present body. I have observed that it is a common practice of the Chairman of the initial meeting of a photographic society to give a more or less succinct account of the rise and progress of the art from the time of Robert Boyle, who first observed that silver chloride darkened on exposure to light, down to the present day. I trust you will agree with me, however, that this is a custom which, on this occasion at least, will be more honoured in the breach than in the observance. I would prefer to say a word or two on what I conceive to be the functions and uses of a society such as ours. Primarily we are, of course, a mutual improvement society. One of our main objects is the dissemination amongst ourselves of knowledge of all matters relating to photography. We meet to exchange ideas and opinions and to give and solicit information respecting such of the various branches of photographic work as our members have been or may be engaged upon. There are, as you are aware, various modes by which this object may be secured, such as exhibitions, *conversazioni*, lantern exhibitions, short papers, the question-box, &c. There is, however, one other function which it appears to me a society such as this ought to have if it would make any pretension to be a photographic society in a real sense. We should never lose sight of the fact that of all the pictorial arts photography has the most direct and immediate connection with physical science. Photography is essentially a branch of applied chemistry and physics. Everybody, of course, recognises this, but from what I can gather from a perusal of the contributions to our various metropolitan and provincial societies and of the discussions which follow them, as these are reported in the photographic journals, all is not done that might be done towards the solution of many of the problems which are essentially connected with the scientific or, rather, the theoretical side of photography. Let me take an example: it is known that a gelatino-bromide plate after exposure will, if kept in the dark, gradually lose that impress which we call the "latent image," so that after a certain length of time it may be re-exposed without a trace of the original impression being visible on treatment with the developer; but, practically, nothing is known of this phenomenon beyond the fact, and yet a dozen questions instantly suggest themselves in connection with it. It would be interesting, for instance, to determine the conditions under which the destruction of the latent image occurs. Is there any connection between the length of time and the sensitiveness of the plate? Do all the haloid salts of silver exhibit the same phenomenon and to the same extent? I have no doubt whatever that a systematic examination of this problem would afford us a great amount of information concerning the true theory of the formation of the latent image, and would, in all probability, have important practical consequences on the preparation and development of gelatine plates. Again: can anybody say that the true theory of the conditions which determine sensitiveness is accurately known? We have learned by practical experience that one among several possible conditions is prolonged heating of the emulsion; but is anybody prepared to say that he accurately knows what this means? Now, this question of sensitiveness is certainly susceptible of being resolved by systematic attack. No doubt, in this special case, the problem presents considerable experimental difficulties; but I should imagine, on trial, it would be found to quickly resolve itself into two or three comparatively simple issues. But there is no lack of questions relating to the scientific, and especially the chemical, side of photography—many of which are possibly simpler in character and admit of more ready solution than that of sensitiveness—which await answer. Now what, therefore, I think this Society might usefully do, among other things, is to try and cultivate the scientific and experimental side of photography. No doubt some of the problems which might be started would require the resources of a well-equipped chemical laboratory to solve them; but there are a large number of others which might be attacked by the apparatus and chemicals ordinarily found in the work-room of a photographer. The number of scientific workers in photography is really very small, and yet all the great advances in the art are due to their labours. The field is by no means exhausted; indeed, I do not know any branch of applied chemical physics which seems to be so rich in promise to the intelligent worker. But I am quite aware that there are many, and no doubt the majority, who approach photography from an entirely different standpoint; they are attracted to it simply from the artistic side or, if you like, from the pictorial side. Others, again, take up photography as a helpmate to their other work. The biologist concentrates his energies on microphotography, and the lecturer on physical science cares only for the production of lantern transparencies. No doubt those who regard photography solely from the artistic point of view, and whose main object is to get striking or brilliant pictures, will have little active sympathy with the scientific aspect of their work. It is a perfectly trite observation that the scientific and artistic perceptions are rarely united in the same individual. It is probably from this cause that the scientific side of his business is so generally neglected by the photographer. But we welcome the artist and the specialist with no less cordiality than we do the man who attempts to throw light upon the occult mysteries of our art. To some there is, no doubt, as much mental satisfaction in tackling with success an awkward or a striking "bit" of landscape, or in recording an admirable piece of composition in a technically perfect manner, as there would be in the discovery of a new fact. To such our Society offers the promise of the fullest appreciation; and even on this side of its work I hope our Society will bear permanent fruit. Why should we not attempt by our joint efforts to illustrate our county in a manner that has never been attempted before? Few counties in England are richer in natural beauties than Yorkshire, and certainly none is richer in historical associations. It would surely not be beyond our powers to attempt from time to time the publication, or at all events the distribution amongst ourselves, of a set piece of illustrative work. Work of this kind, if gone about in a systematic and intelligent manner, might have considerable historical value, and our efforts might not only contribute to the satisfaction of ourselves and to the pleasure of our friends, but be of service to those who come after us.

The address was very warmly received, and at its conclusion Messrs. Teasdale, Ramsden, Branson, &c., joined in the discussion.

The following exhibits were made:—Multiplex camera back, by Messrs. H. and E. J. Dale, London; portable camera as used thirty years ago, by Mr. J. W. Ramsden; instantaneous shutters, by Mr. A. A. Pearson; a carrier for lantern slides, a universal joint for camera finder, a series of fifteen gelatino-chloride plates showing gradation of colours from black to ruby (own emulsion), by Mr. T. W. Thornton; lantern slides, by Mr. W. Denham and Mr. W. Teasdale; and silver prints, by Mr. H. Rodwell.

The following questions were taken from the question-box and suitably discussed:—1. Is the presence of ferric oxalate any advantage in the ordinary ferrous oxalate developer?—2. Is there any disadvantage in using the hypo. bath for fixing after it has become discoloured from constant use?—3. Is there any advantage in using alum in the fixing bath for gelatine plates?

The meeting was shortly afterwards adjourned.

DUNDEE AND EAST OF SCOTLAND PHOTOGRAPHIC ASSOCIATION.

THE fourth regular meeting for the present season was held on Thursday, the 3rd inst., in Lamb's Hotel. There was a good attendance, about forty members being present. In the absence of the President, Mr. G. D. Macdougald occupied the chair.

The minutes of last meeting having been read and approved, the seven members proposed at last meeting were admitted, the membership now numbering close on 100. Four new applications were handed in.

Mr. JOHN THOMSON read an interesting paper on *A Question in Photographic Optics*, which was listened to with attention, and a hearty vote of thanks was passed to Mr. Thomson.

Mr. Magnus Jackson, Perth, sent a number of pretty snow scenes, which were much admired.

Some time ago it was suggested that a dark room be fitted up in connection with the Society for the use of those members who might not be able to have a dark room at home, and Mr. J. C. Cox, President of the Association, made a handsome offer to the Society to get a suitable room fitted up at his own expense. This has now been done, and a room in Reform-street will shortly be opened, those members wishing to avail themselves of it paying five shillings per annum. The dark room has been fitted with sinks and gas and water connections, and it is expected it will be taken advantage of by a large number of the amateur members.

The next popular evening is to be held in the Y.M.C.A. Large Hall on Wednesday the 30th inst. Subject: *A Tour in Bavaria and the Tyrol*, by the Secretary, Mr. D. Ireland, Jun., illustrated by about seventy photographic lantern transparencies.

HALIFAX PHOTOGRAPHIC CLUB.

THE monthly meeting of this Society was held on Tuesday, the 8th inst.,—Mr. T. Birtwhistle, President, in the chair. The ordinary business of the evening was postponed to enable the Chairman to introduce the subject of the proposed exhibition.

After a lengthy discussion as to the rules to be observed, the number and classes in which prizes should be offered, and the question of the jury considered—all of which were satisfactorily settled—it was unanimously decided that the exhibition should be held as early as arrangements could be made, and a committee of management was appointed to settle all details.

The question-box was found to contain the following query:—The opinion of the Society is solicited as to the relative merits of ferrous oxalate on the one hand, and alkaline pyrogallic on the other, as developers, more especially bearing on the latitude each afforded for meeting the extremes of over- and under-exposure.

Mr. ILLINGWORTH, Mr. DAVIES, and Mr. SMITH (of Sowerby Bridge), in offering their opinions as professional photographers, concurred in giving preference to the alkaline pyro. developer. Their experience was that if the exposure were not finely hit upon there was a great difficulty in producing a good negative, and the loss of time involved under such circumstances meant to professionals money as well as inconvenience. When a plate required forcing the results would be harsh and hard. Mr. Illingworth was, however, able to counteract this evil, to a certain extent, by reducing the ferrous salt and increasing the oxalate of potash. He was also under the impression that up to a certain point an under-exposed plate developed quicker with ferrous oxalate than with pyro., but, beyond this, much slower. Pyro. certainly held the palm when taken as an all-round developer.

Mr. J. E. JONES believed that when strong contrasts of light and shade were desirable—*à la* Rembrandt, for instance—ferrous oxalate was the best; but he pinned his faith to pyro. for general purposes.

Mr. E. GLEDHILL liked pyro. best, because of the greater latitude it afforded by modification; however, when good blacks were required, as in the case of transparencies, then ferrous oxalate was to be recommended.

Mr. BULMER had heard a great deal said about pyro. staining; but he could get as clean and bright negatives with pyro. as it was possible to do with ferrous oxalate. Most advocates of the latter principle made much of this evil; but in his experience stains could be produced with any developer if not used intelligently. He was not prejudiced in giving this opinion, but he preferred pyro. on account of the great power it afforded for regulating the character of the negative.

Mr. COUNCILLOR SMITH well knew there would always be exponents of, or advocates on, both sides of the pyro. and iron question, and it was only natural that parties should stand up for the one that pleased them the most. He would point to the striking fact that on the continent ferrous oxalate as a developer reigned almost supreme, being used by a large body of workers eminent in their profession. There could be no question that France, Germany, and Italy could compete favourably with the very best results produced in England; and he was sure the iron developer was not properly appreciated on this side of the channel because it was very imperfectly understood. One of the chief causes of failure was attributable to development being stopped too soon. He allowed the action to proceed until all trace of a picture became lost to sight. When viewed by reflected light, in fact, the plate should appear dense to blackness. When fixed such pictures would be found to possess all the qualities necessary for a good negative. Possibly many who tried the ferrous oxalate in its early days, being a new thing and almost an innovation, put it aside condemned without sufficient trial, and he felt confident that if it had received anything like the same amount of study or attention bestowed upon pyro. it would today have held the place of honour in the first rank of developers. As regards latitude, he claimed for it everything that could be conceded for the alkaline method. Dr. Eder, and other eminent scientists, distinctly stated that any amount of latitude was obtainable, and if he (Mr. Smith) erred in this, his own, conviction, it was one consolation he did so in distinguished company. Dr. Eder's concentrated iron developer certainly gave as much latitude for forcing as ammonia did, and that without its drawbacks. Mr. Williams once made the suggestion that two plates of the same description should be exposed, or, rather, under-exposed, and afterwards developed with pyro. and iron respectively. If this were carried out, he (Mr. Smith) was confident the sequel would be the means of removing much misconception. The proportions he generally adopted were one part of a saturated solution of iron to four parts of saturated solution of oxalate of potash, varying at times from one to three. He began development by using very little iron, gradually increasing the quantity as development proceeded, removing the plate as each addition was made. For bromo-argentic paper he used half-an-ounce of iron solution to three and a-half ounces of oxalate, added to about twenty-four ounces of water. Referring to Mr. Gledhill's remarks, he (Mr. Smith) thought the colour of a transparency depended as much on the character of plate used as on the developer. He had obtained beautiful warm brown tones with ferrous oxalate. He had tried Newton's soda developer, but had not succeeded in getting negatives free from a yellow cast of stain, which deepened if any forcing was attempted.

The CHAIRMAN agreed with all Mr. Smith had said in favour of the iron developer. It was a magnificent discovery, and he believed it to be the developer of the future. He was at a loss to account for so much conflicting evidence, for he had never found it weak or wanting, although he only used one part of iron to eight of oxalate. He liked slow development, often getting the best results by first bringing out the details with an old and almost worn-out developer, and finishing off with a new one. He believed the real meaning and bearing of a "saturated" solution to be only imperfectly understood, and did not think the mere dissolving of the oxalate or iron until crystals remained deposited was a saturated solution, giving the greatest concentrated developing energy possible. The addition of citric acid was a grand step forward, altering all this wonderfully. If both solutions were not perfectly saturated a precipitate would be the result of bringing them together, to the sacrifice of developing energy.

Mr. W. C. WILLIAMS, while acknowledging he had not given Dr. Eder's modified developer a trial, conceded a high place to ferrous oxalate. Still he felt bound, by past experience, to give his unprejudiced verdict in favour of alkaline pyro. He agreed with the previous speakers who attributed a greater latitude to the latter; but although this was a great power to recommend a system, he was afraid, however, that undue prominence had been given to this aspect of the question, while the quality of results had to some extent been lost sight of. He believed that iron had a stronger proportionate affinity or energy for developing the higher lights, and rapidly bringing these out, than for parts acted upon more feebly by light, and, consequently, a want of roundness followed its use. With pyro., the conditions being different, the high lights and deep shadows are brought forward more in harmony with one another, a wider scale of light and shade following. This irregularity of action, or special affinity, as he termed it, was also marked in other chemical operations in connection with photography. He quite agreed with the Chairman as to slow development, but always liked to complete this part of the process on the "same day of the month" it was commenced, which did not happen on one occasion when using ferrous oxalate. When using pyro., and under-exposure was suspected, a preliminary soaking of the plate in a four-grain solution of pyro. having the least possible trace of ammonia, but no bromide, previous to development proper, would be found advantageous. And, again: soaking the plate in the ammonia solution for some time, and, after washing, soaking in pyro. having a trace of bromide after well washing, is another good plan. For many years he had used glycerine and water to soak plates in (glycerine two parts, water twenty) for about ten minutes before developing. This prepared them for the even and rapid action of the developer to the back of the film, and so tended to reduce the amount of ammonia used. He gave it as his opinion, however, that no amount of dodging or patience ever made either an under- or over-exposed negative a good one.

The thanks of the Society was then passed unanimously to the proprietor of THE BRITISH JOURNAL OF PHOTOGRAPHY for the Journal forwarded during the past year, and for the current ALMANAC. Also to the *News* for the *Year Book* to hand.

A very instructive evening was then brought to a close.

Correspondence.

RECOVERING SILVER FROM OLD COLLODION FILMS.

To the EDITORS.

GENTLEMEN,—Having noticed in last week's Journal an inquiry as to whether collodion films washed off old negatives are of any value, and thinking it may interest some of your readers, I venture to give my experience.

I cleaned some hundreds of negatives with common washing soda and water, boiled down the residue in an iron pot, and heated till red hot; then smelted in a clay crucible, till white hot, for half to three-quarters of an hour. I then removed it from the fire and let it cool for ten minutes or so. Wishing to cool quicker, I immersed the pot in a bucket of water, and in about twenty seconds it began to give indications of trouble. I then made myself "scarce"—not any too soon, as a most violent explosion took place, rending the iron bucket and blowing it out of shape, actually making holes in the iron.

This, in my opinion, is rather a dangerous experiment, and, considering I had only about a pound of residue (including a good percentage of soda), what might the consequences have been with more? I have since reduced successfully a portion of the same residue, by mistake omitting the cold water bath.—I am, yours, &c., FREDK. T. WEBB.

11, *Portland-place, Wolverhampton, January* 15, 1884.

A CORRECTION.

To the EDITORS.

GENTLEMEN.—Allow me to correct an error inadvertently made by me in your issue of last week regarding Mr. A. Cowan's gelatino-chloride plates. I said in that article that the *manufacture* of these plates had passed into the hands of Messrs. Marion & Co.; but Mr. Cowan kindly informs me that the *business arrangements only* have passed from him, and that, as I understand, Mr. Cowan himself continues to prepare the plates. In future, therefore, time and trouble will be saved by applying to Messrs. Marion and Co. direct for these plates.—I am, yours, &c., ANDREW PRINGLE.

Craigcleugh, January 16, 1884.

PHOTOGRAPHIC EXHIBITIONS.

To the EDITORS.

GENTLEMEN,—I think with Mr. E. Dunmore that there is much necessity for revisal of the present method of treating the pictures sent to photographic exhibitions; although, had the matter not been immediately on the *tapis*, it was not my intention to allude to the following case in point.

At the request of the Secretary of the Newcastle-on-Tyne Photographic Association, I promised to send to their last exhibition half-a-dozen pictures which I had then at Pall Mall. As there was very little interval between the closing of the latter and the opening of the Newcastle display, it was only with considerable expense and trouble that I got them to the exhibition gallery by the first hanging night. As I was in Newcastle at the time I took my pictures there personally, and the exhibits were just beginning to be arranged when I arrived. I drew the attention of one of the Hanging Committee to them, and explained to him that, while I had no intention of biassing his judgment as to *where* my exhibits were to be hung, yet I had arranged the subjects, taken them, and framed them all with a view to their being companion pictures, and I should be glad if he would allot them a place together in the ample space at his command. His reply was worth noting. He said that *he* saw no reason for their being hung together, and, besides, he could promise no such thing, *as there might be odd spaces which they would help to fill!* Accordingly, this gentleman in a few minutes afterwards proceeded to fill a couple of these same odd spaces with two of my pictures, and I am convinced that the other four were only saved from a similar fate through the intervention of one or two others of the Committee.

I do not wish to allude to the discourtesy of this gentleman, so I shall keep my opinion to myself. But I should like to ask if the system is not deserving every censure which makes it a case of sheer chance whether the efforts of the essayist receive scant justice or are worse than rejected; for, to see all the subtleties with which he has endeavoured to breathe art life into the (in itself) inanimate photography wantonly shattered at the pleasure of the unthinking or incompetent hanging committeeman, is surely death to those noble ambitions and efforts which do more than all besides to elevate photography to a prouder position.—I am, yours, &c.,

Victoria House, Upper Bedford Place, W.C. LYDDELL SAWYER.

January 15, 1884.

MR. ANDREW PRINGLE AND "GELATINO-CHLORIDE FOR TRANSPARENCIES."

To the EDITORS.

GENTLEMEN,—In the Journal of last week I read with much interest Mr. A. Pringle's article on *Gelatino-Chloride for Transparencies*, and thank him for it. Yet there are in that article one or two things I should like to comment upon.

He says he does not recommend gelatino-chloride plates for camera work, but exposes in *contact* with a negative, and an unvarnished one by choice. I should like to ask him by what means he retains them in contact (say a 10 × 8 negative) in a pressure-frame? Seeing how many good negatives there are on gelatino-bromide plates, the glass of which is so uneven that it is a risky affair to print them with silvered paper, how much more in contact with another glass! Would that be advisable? And, again: how would he manage an unvarnished collodion negative?

I agree with him that a positive on glass far transcends a positive on paper, and, there is little doubt, would meet with a ready sale. Yet I would ask him—Would it be advisable for a photographer, who having at considerable cost of time and labour secured a good negative, to sell glass transparencies from it, thus putting it in the power of others to reproduce negatives from it, and it might, and probably would, enable them to compete with him in the market?—I am, yours, &c., DEMARR.

January 15, 1884.

A TRADE QUESTION.

To the EDITORS.

GENTLEMEN,—I am informed that a large wholesale firm of dealers in general photographic materials has entered into arrangements with a well-known West-End co-operative stores to supply them with finished enlargements, which are retailed by the stores at an advance of 4s. on the wholesale price charged to the members of the profession. Now I should like to ask the profession if they think that a wholesale house is acting fairly by them, in thus indisputably taking away their most profitable work?

If my information be correct, I should surmise that photographers will not care to deal with those who, not satisfied with doing a wholesale business, seek to undersell the whole profession in this and, I firmly believe, in every other branch of our business.—I am, yours, &c.,

January 14, 1884. X. Y. Z.

PHOTOGRAPHY IN ITALY.—In the course of an article on *Travels in Search of Sunshine*, the *Daily Telegraph* speaks as follows of the state of photography in Italy:—But the mild climate and society-loving patrons of the Roman season are a very different class from the sightseer, and these again may be divided into two sections. The first I may call the flying sightseers, the second the sedentary ones. The former gallop through the city, so to speak, rushing literally from pillar to post—from St. Peter's to the Lateran, from the Pantheon to St. Paul's without the Walls, from the Coliseum to the Baths of Caracalla, from the Tomb of Cecilia Metella to the Catacombs, from the Forum of Trajan to the Vatican, from the Ponte Molle to the Pyramid of Caius Cestius. "The Capital," once significantly remarked Pio Nono, in a political harangue, referring to the seizure of Rome by the Italians, "is close to the Tarpeian Rock." The flying sightseers "do" the Campidoglio, its museum, the Church of the Ara Cœli, and half a dozen more churches to boot in the course of a single morning; and when you meet them in the evening at the *table d'hôte* they enumerate the achievements of the day as though the sights which they had seen were so many scalps ravished by ruthless tomahawks from inimical skulls, and to be dried and hung up as trophies in their lodges in the far distant West. Other substitutes for scalps do they find in the amazing number of photographs which they purchase. Commercially, I should say that a photograph all the world over is an article which can be produced at the cost of about a penny, and which is sold at from a shilling to eighteen-pence. Somebody must be making a vast fortune every year by the sale of Roman photographs. They beat the Neapolitan ones—those of Pompeii excepted—most signally. The Bay of Naples does not photograph well, and Vesuvius under the sun's pencilling comes out but poorly. The modern architecture of Neapolis is uninteresting; the huge Royal Palace resembles a barrack; the façade of the San Carlo is vast, but not imposing; and the exteriors of the churches are naught. The costume of the people is as deplorably ragged as ever, but it has ceased to be picturesque. But at Rome everything, with the exception of the staring brand new houses in the Via Nazionale and the new quarter of Macao is worth photographing. There are said to be 11,000 rooms in the Vatican; and, could they be all photographed, I have little doubt that customers could be found for prints of every *loggia* and every *stanza*. It is pleasant to think of so many thousands of these photographs—ruins, churches, palaces, aqueducts, obelisks, fountains, tombs, pictures, and statues going to embellish the apartments of brown-stone houses with marble façades at Chicago or on "Nobs' Hill," San Francisco; but at the same time the artistic sense grows a little wearied when in the most frequented streets of Rome every other shop seems to be one for the sale of photographs. The Romans, however, may with justice plead that photograph selling is extremely profitable. A Roman shawl of brightly-dyed silk, a Roman bronze of the Triumphal Augustus, and Roman jewellery and mosaic work, cannot, I should say, be sold at a profit of more than 150 per cent. But a much wider margin of gain is presented by the photographs, which in such astonishing profusion are vended to the flying sightseers.

Notes and Queries.

I HAVE frequently seen reduced etchings of large engravings executed in a nice, open style. I should greatly like to know by what means they are produced.——PHOTOTYPER.

HAVE working directions for preparing extra sensitive collodion emulsion plates by Newton's process ever been published by that gentleman in America or elsewhere? And will any one who is conversant with its details kindly afford a little information?—GEO. S. KING.

G. B. B. inquires:—"Is there not an omission in the No. 4 formula for the dusting-on process on page 227 in the ALMANAC for this year? Ought there not to be some water?"——In reply: It will be found to be all right by the addition of an aqueous solution of bichromate of potash—one ounce of the salt in a pint of water.

DEAR SIR,—I have several pupils in photography, and the method I recommend them to adopt is to bring their negatives to me, and I then develope them in their presence. You may guess the erratic exposures that they sometimes give, and I often feel at a loss when one negative, perhaps, will scarcely come up with any amount of forcing, while the next springs into existence at once. The former class take care of themselves, but the latter do not. What is the best plan to adopt in developing that, without losing too much time, I may get through a good number of plates in a reasonable time, and yet not lose the grossly over-exposed ones? If any of your readers can help me I should be much obliged.—TEACHER.

A. B. asks:—What is the best way of utilising plates exposed to full light by custom house officers or others? Will bichromate of potash, weak chlorine water, or weak acid nitrate of silver render them useful for any purpose whatever? He also asks:—Will any substances but alum harden gelatine; which other substances produce no opaque precipitate with hyposulphite of soda or anything contained in ordinary pyrogallic developer?——In reply: We should like to have the opinions of any correspondents who have acquired a practical acquaintance with what we may term the art of de-illuminating dry-plates, either by treatment with a solution of bichromate of potash or otherwise. We have employed this solution with good effect, but never yet in a manner sufficiently systematised to warrant our writing concerning its advantages.

THE best way for X.Y.Z. to satisfy himself as to the existing non-necessity for having his glass interposed at a right angle to the direction in which the light falls upon the sitter, is to hold up in front of him a clean plate of glass and examine any object, such as a piece of printed matter, through it. When it is held quite squarely the light upon the paper is seen at its very best; but if he turn it in a slanting direction he will not fail to observe that a very considerable deviation from perfect squareness takes place before any diminution in the amount of light transmitted can be observed. This, I think, affords X.Y.Z. an answer to his query.—J. H. F.

WITH reference to the degree "Ph.D.": it is not at all necessary for "Aspirant" to incur any trouble or expense connected therewith if he be serious in regard to the alternative intended by him. He has merely to affix the letters to his name in the absolute certainty of no one putting himself to the trouble of investigating the truth or falsity of the claim. There is no moral difference between adopting this course and that of giving twenty pounds to the agent of the Philadelphia bogus diploma manufacturer who was lately "run to earth" by the local police for his practice in "degrees" *in absentia*. Why should not "Aspirant" aim a little higher and dub himself "Professor" or "Colonel" or even "General," according to use and wont in certain countries of the world?—M.A., (Oxon).

Exchange Column.

I will exchange a powerful binocular field glass for a bellows-body camera or anything useful in photography.—Address, PHOTOGRAPHER, Fore-street, Abingdon, Berks.

Stoves: George's patent gas calorigen, £3 3s., for £2, tortoise slow combustion, cost £2, for 30s., or exchange; used three months only.—Address, G. P. ABRAHAM, Keswick.

Wanted, in exchange for a pair of short focus rectilinear lenses, by a good maker, a 5 × 4 camera, for dry plates, with double backs.—Address, F. W. DEW, Norton-street, Jesson-street, Coventry.

I will exchange a splendid dark tent, on wheels, for anything useful in photography; camera and lens preferred; difference in price adjusted.—Address, J. LEACH, Dolgelly, Merionethshire, N. W.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

Vero—Write to Messrs. Marion and Co. They supply the Warnerke sensitometer.

N. Solter.—About a drachm of the emulsion to each quarter-size plate will be sufficient.

Charles G. Williams.—You do not say what surface you wish to sensitise, so how is it possible to answer your query?

J. Wagstaff.—It is clearly the fault of the limes; they are very inferior. Procure another sample, and from a different source.

J. H. Reinhold (Cincinnati, U.S.A.).—Thanks for seasonable greetings and good wishes. Your instructions shall have attention.

W. H. Sherman (Milwaukee, U.S.A.).—Your instructions shall be carried out. Thanks for your high opinion of our journalistic labours.

A. Venic—If you send the prints to us, together with one-and-sixpence for each one, in postal orders, we will effect the registration for you.

A. B. C.—See The British Journal of Photography for July and August, 1879. We cannot, in this column, devote the space to giving lengthy formulæ.

Victoria.—If you do not know a member of the Society who will propose you as a member write to the Secretary, and he will doubtless propose you for membership.

George B.—Although the mount bears the name, the glasses were not made by that optician. The mount is genuine; the lenses not. The lens is returned by parcels post, as requested.

R. R. Burrows.—You will find a solution of the perchloride a far better and more agreeable etching fluid for copper than nitric acid. Try it, and you will find several of your troubles disappear.

W. Rubens (Elberfeld).—The instructions and copies of advertisements have reached the Publisher, but not the remittance referred to. On receipt of the latter (if found sufficient) the order will be carried out.

A. S. Sexton.—Ordinary enamelled paper, such as that employed by lithographers, will answer quite well. Messrs. Spicer Brothers, Bridge-street, will supply it. Get the hardest that is made, as that will answer best.

Oliphant.—Better purchase a cheap manual on electrotyping. That will give you all the information you require. We cannot afford sufficient space in this column to give such practical details as would be of assistance to you.

H. Couch.—1. Try filtering the emulsion more carefully, having previously allowed it to stand for a quarter of an hour in hot water. This will frequently prevent the formation of the "scum."—2. The method is equally adapted for the preparation of slow plates. Boil for a shorter period, and either add ammonia or else bring the silver and bromide in the emulsion as nearly as possible to the point of neutrality, when the silver bromide will subside very rapidly.

R. D. N. B.—1. The lens will do quite well.—2. All will depend upon the density of the negatives. No definite time can, of course, be given.—3. A formula is supplied with the paper; you had better keep to that.—4. Either way, according as you require a correct or reversed position.

M.—The slight yellow stain on the negatives will not interfere with your producing good transparencies from them suitable for the lantern; that is, if they, as you say, produce good and brilliant prints on paper. The only disadvantage of the stained film is that a slightly longer exposure will be necessary.

Pyro.—All will depend upon how you effected the reduction with the perchloride of iron. If you treated the negatives with hyposulphite of soda after the perchloride, we fear you will not succeed very well. Try intensifying with silver in this case. If the hypo. were not used then ferrous oxalate will doubtless answer quite well.

T. Clarke (Brighton).—We have distinctly stated, on several occasions, that the Publisher is not—will not be—responsible for specimens enclosed to advertisers in these pages. He has interested himself before in order to have specimens returned—sometimes successfully and at other times unsuccessfully. He will endeavour to trace those alluded to by our correspondent, and, if possible, have them returned.

H. N. Bates.—1. The *data* are too slight to enable us to form an opinion. Try longer boiling.—2. The emulsion should give a clear picture immediately after boiling, though frequently a slight veil may be present at that stage which clears off afterwards.—3. The means you have adopted seem to be suited to the purpose. See the report of the last meeting of the London and Provincial Photographic Association.

A. C. M.—1. Plain collodion may be used as a makeshift; but it should be of a very porous character. You will find it best to employ what is recommended.—2. Yes; the film is very hard indeed.—3. The plates will keep for years if kept in a dry place. If, in place of employing opal glass, you had used ground glass, you would have found it answer the purpose, and with this additional advantage a shorter exposure would have been required.

R. W.—1. The same form of condenser employed in the ordinary lantern. They may be had of any diameter up to eighteen or twenty inches.—2. The use of the condenser is to concentrate the light. If you dispense with the condenser and substitute ground glass, you will have to give a much longer exposure.—3. The distance of the light is dependent upon the focus of the condenser.—4. An ordinary concave reflector may be employed.—5. The oxalate of potash will keep in solution. The iron undergoes a change by keeping.—6. Yes; to get the best effects.

E. Yeoman.—The proportions of your present studio appear to be very good, except, perhaps, it may be a little too high. If you had stated the aspect of the building it would have been better. Certainly, from the photograph, we can see no reason why portraits taken in such a studio should be hard, as we should imagine that in a room such as you at present have, any effects of light and shade could be produced with a little management of the blinds. It is more a question of lighting the model than the construction of the studio in this case. If in the new studio you make the roof lower, we should advise you to have the same amount of light stopped off at the ends as at present. The prints enclosed are very nice, indeed.

In Type.—Communications by W. E. Debenham; Herbert S. Starnes; G. H. Martyn; A. Donald; "Free Lance."

Photographic Society of Great Britain.—The next monthly technical meeting of this Society will take place on Tuesday next, the 22nd instant, at 8 p.m., at the Gallery, 5a, Pall Mall East.

Photographic Club.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 23rd inst., the subject for discussion will be—*On the Production and Use of Sky Negatives.*

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician,
For two Weeks ending January 16, 1884.
These Observations are Taken at 8.30 a.m.

JOURNAL OF PHOTOGRAPHY.

No. 1238. Vol. XXXI.—JANUARY 25, 1884.

POTASSIUM BICHROMATE AND THE UNDEVELOPED IMAGE.

In our *Notes and Queries*, last week, an inquiry as to the best means of utilising sensitive plates spoilt by accidental exposure to light induced us to make a few systematic experiments in connection with bichromate of potassium upon plates which had received various exposures to light. The results arrived at are sufficiently interesting to be placed on record.

Captain Abney was the first to point out that most oxidising agents act as destroyers of the latent or undeveloped image—notably bichromate of potash, ozone, nitric acid, and permanganate of potash. With gelatine plates the first of these is, for various reasons, the only one which is practically applicable, though with collodion films we have proved the correctness of Captain Abney's observations. Our experiments were, therefore, confined to the bichromate.

For some time it has been the practice of many emulsion workers to submit the solidified emulsion, at a certain stage of its preparation, to the influence of a ten-per-cent. solution of potassium in order to remove any chance veil or fog arising from stray light in the preparing room. This purpose it, no doubt, answers admirably, and it has come to be believed that bichromate is capable of entirely undoing the action set up by light—a view which, so far, our experiments go far to contradict.

The first experiment was made by exposing one half of a plate to diffused daylight, in an ordinary room, for three or four seconds. It was then cut into a number of strips, one half of each of which had received exposure. These were immersed in a five-per-cent. solution of bichromate of potash for periods varying from one minute to one hour, and then very thoroughly washed in several changes of water for at least another hour. The whole were placed together in a dish and developed simultaneously with ferrous oxalate, when every strip showed distinctly the mark of exposure, the different periods of immersion having successively made the impression weaker in proportion to the prolongation of the action. The deposit formed upon the strip which had had one hour's immersion in the bichromate bath was of a decidedly stronger type than would be described as "fog," being strong enough for the half-tones of an average negative. It should be remarked that the development was prolonged until all further change appeared to have ceased.

From this it seemed that, so far as a comparatively strong impression of light is concerned, a solution of ordinary strength of bichromate of potash is incapable of removing it; or that, to bring about that end, it is necessary to employ a stronger solution, or to greatly prolong the duration of its application. In order to test to what extent impressions of varying degrees of strength are affected by treatment with bichromate, a number of similar exposures were made under a Warnerke sensitometer screen. A plate was cut up into fragments two and a-half inches square (sufficient to cover the whole of the figures), and these were exposed successively under the standard conditions to the light of the phosphorescent tablet. They were then immersed in the five-per-cent. bichromate solution, as before, for periods varying from one minute to sixty, and thoroughly washed, one square being left unbichromated for comparison. The whole series were developed simultaneously in fresh ferrous oxalate the action of which was allowed to continue for two hours until all further developing action had long ceased.

After careful washing the plates were examined, unfixed, in daylight, when the unbichromated square exhibited No. 20 very distinctly and 21 faintly, the general image being bold and vigorous. But, upon examining the remainder, we were surprised to find that every one, even to the longest immersed in the bichromate, showed No. 20, the images, however, becoming feebler and presenting less contrast between the different tints in proportion as the immersion in the bichromate had been longer. So feeble were the higher tints, indeed, that after a short exposure to daylight several of them were entirely masked by the discolouration of the film, especially when examined by reflected light.

An interesting fact in connection with the image produced upon the bichromated films is that, despite the prolonged development, it is confined almost entirely to the surface, and except in the case of the very shortest immersions in the bichromate is entirely invisible from the back of the plate. It is possible that this may have arisen from the presence of traces of bichromate which had escaped elimination from the under layers of gelatine. If this be so, then the question arises as to how far *perfect* elimination of the bichromate would destroy its action on the image. A plate immersed in the bichromate for one minute and then merely rinsed under the tap for thirty seconds or so exhibited far more of the bichromate influence than another immersed for one hour and well washed.

But if bichromate alone be practically insufficient to undo the effect of even faint impressions of light, it is different with solutions containing free chromic acid. A five-per-cent solution of bichromate to which a few drops of sulphuric acid were added was found, after one minute's immersion, to have completely destroyed the image, or, at least, to have put it beyond the reach of the developer, even after several hours' action.

Now, though in the above experiments bichromate has been shown to fail in destroying the impression of light, it does not follow that it is not useful as a fog-remover, inasmuch as the conditions may be entirely different. If the fog to be removed be but slight, and no subsequent forcing be resorted to in development, it is pretty certain the treatment with bichromate will suffice, as we have proved by bichromating, washing, and re-exposing a plate successfully. But where it is desired to entirely eliminate any previous impression of light free chromic acid must be resorted to.

CAMERAS FOR FLYING SHOTS.

It was a fundamental article in the photographic faith of the late Mr. J. R. Johnson that camera stands were quite a mistake in all cases in which instantaneous views were to be taken by means of small cameras.

This, too, appears to be the opinion of an American photographer, who has obtained a patent in that country for a gun-stock attachment to a camera, by the aid of which the camera is aimed at the object to be captured. By means of some mechanism not explained, but the nature of which one can readily guess, the trigger of the gun-stock is attached to the lever by which the drop or instantaneous shutter is actuated, and thus when the camera has been brought "to the shoulder" and the central point of the subject sighted, the trigger is touched and the picture secured.

From what we have just written the more experienced readers of the Journal will already have recalled the "pistolgraph" by which Mr. Skaife, more than twenty years ago, obtained numerous charming little instantaneous views. This camera being constructed in the form of a pistol, and operated in a manner somewhat analogous, was the source of many clever *bon mots* which appeared in the comic serial literature of the period, especially with reference to the capability of the instrument for "shooting" or "pistolgraphing" babies.

With a view to test the capabilities of the gun-stock attachment we lost no time in securing, from a second-hand gun shop, an old rifle, which was quickly *dis*barreled, and the stock, after a few alterations, attached to the base-board of a 5 × 4 camera, a string being employed to connect the discharging bolt of the shutter with the trigger. This answered quite well; but we found the gun-stock an effectual barrier to the employment of the camera in public, in consequence not merely of its weight and shape, but of the unwelcome degree of attractiveness discovered in it by the public, and especially by the omnipresent "small boy." For these reasons —especially as we had found an equally effective and less obtrusive substitute—we laid aside the gun-stock, adopting in its stead a thick, short, round handle, which we screwed into the bottom of the camera, and grasped with the left-hand when taking a picture. This we found to answer the purpose of supporting the camera exceedingly well when about to take a flying shot at a subject.

But out of this has been evolved the still simpler and equally excellent method of employing the camera without any addition whatever. The camera is grasped by both hands, and by means of sights placed on the top the object intended to be in the centre of the picture is brought into line, the forefinger of the right hand being in convenient proximity to a lever or trigger which projects slightly below the bottom at the right side. By this arrangement instantaneous views may be taken having the subject as well arranged on the plate as if the camera had been carefully erected upon a rigid stand susceptible of every adjustment.

Those who try this method of taking instantaneous views without the stand will not only be surprised at the ease with which it can be done and the sharpness of the negatives, but will also discover that the sighting of the central object in the composition may be accurately effected by glancing along any of the corners of the camera.

COMBINATION PRINTING.

Redeeming the promise we gave in our last issue, we shall now proceed to describe the method employed by M. Lambert in combination printing in the carbon process—or we might, perhaps, more correctly have said "one of the methods;" for we believe that gentleman frequently introduced considerable modifications in his plan of working in order to attain the end in view. However, all the modifications were based on the same general principle. The plan about to be described was the one we had the pleasure of seeing carried out by him at one of his demonstrations, and, although in this instance it was simply changing one background for another, yet we learnt that in more complicated cases the same principle was always adhered to.

Before proceeding farther, it may be well to explain to some of our younger readers that, at the time they were first shown, the results produced by M. Lambert excited the greatest interest. The enlargements exhibited by him—many of them from paper prints—had all the appearance of being most elaborately finished; yet the prints themselves were absolutely untouched, as the whole of the retouching was effected on the enlarged negative and intermediate transparency. Not only was one background replaced with the greatest success by another, but, in some instances, the costume of the model was changed or very considerably modified. Indeed, nothing appeared to be too difficult for him to accomplish in the way of double printing, even in carbon. With these few remarks we shall at once proceed to describe the method of substituting one background for another, as we saw it practised.

The enlarged negative employed on the occasion referred to measured about two feet by one foot and a-half, and was of one figure out of a group of several. It was also from a paper print. This negative had previously been retouched according to the Lambert plan. It may here be advisable to explain that this plan consists of covering both sides of the negative—which, by the way, must be a very thin one—with a thin kind of tracing-paper termed "*papier mineral*." On these two papers the whole of the retouching is done, and not on the surface of the negative itself. After the lights have been strengthened, and all the coarser portion of the work done on the back paper with a coarse stump and plumbago, the negative is turned over, and the finer details dealt with on the front paper, a finer stump and a blacklead pencil being used for this purpose.

When the negative is finished, and while it is still on the retouching desk, the outline of the figure is carefully traced over with a blacklead pencil on that paper which is on the reverse side of the negative. This mark is simply to serve as a guide line in the masking. Next, a piece of somewhat transparent yellow paper is laid on the negative, and the outline also traced upon that. The figure is then cut out of this yellow paper, roughly, about a quarter of an inch inside the pencil mark. Then the background is cut out about the same distance outside the mark, so that the figure-mark is about half-an-inch or so less in size than the background one. The negative is now placed in the pressure-frame. In doing this it must be carefully fitted into one of its angles, as we described in another method of masking last week. The tissue, having been carefully trimmed so that its edges are true, is then placed on the negative, and at the same time, also, adjusted accurately in the angle of the frame. This is imperative.

It is necessary to mention here that the glass of the pressure-frame should be somewhat thinner than that with which large sizes are usually fitted; otherwise the light will be more diffused in the printing than is desirable, as the masking has to be done from the outer surface of the pressure-frame glass. The glass of the frame we saw in use did not exceed a quarter of an inch. We have an impression that it was even less than this. Next some non-actinic colour oil paint—such as the Indian red, which is sold in tubes for artists' use—is mixed with olive, or some other non-drying, oil. With this the outline of the background is painted round, on the glass of the pressure-frame, for half-an-inch or so, the pencil-mark on the paper of the negative serving as the guide line. In doing this the outline of the figure is slightly overlapped, and the paint applied somewhat thinner at the edge where it overlaps. The paper background mask, which has been previously described, is then taken and laid on the glass, and kept in position by another piece of glass being laid upon it. The frame is now exposed in diffused light, its position being changed occasionally as the printing proceeds, in order to ensure even diffusion of the light between the paint and the negative. The only object of the roughly-cut paper mask, it may be explained, is to avoid the necessity there otherwise would be of covering the whole of the glass over the background with the red paint, and cleaning it off afterwards—a somewhat disagreeable operation.

The figure being printed the frame is taken in, the paper mask removed, and the red paint wiped off with a duster. If at this stage the print were developed we should, of course, have the figure only with a white background, but, instead of the outline being—as in the case of ordinary masking, when employed in silver printing—sharp and abrupt, it will be graduated off or slightly vignetted. Now, as a second background has to be introduced, it is necessary to protect the already printed figure while it is printing. This is done in the following manner:—Before the negative and tissue are disturbed the outline of the figure is painted round on the glass of the pressure-frame, in the same manner as was done with the background—the same precautions being observed in slightly overlapping the line, and applying the colour more thinly at the edges, as in the former case. This done, the frame is turned over, opened, and the negative and tissue removed. The second negative is now substituted for the first, and arranged in its proper position. This may be judged of by looking through it at the painted outline on the pressure-frame glass. The tissue is then adjusted in the angle, as before, and the frame closed. It is then turned over and the rough figure mask placed in position on the painted outline, as in the case of the background, and the second printing proceeded with—the same precautions as before being taken that the position of the frame is shifted from time to time as it proceeds. After the printing is completed the picture is developed in the ordinary way. It need scarcely be mentioned that on no account must any trace of the oil paint be allowed to get into contact with the surface of the tissue, or it will be sure to cause blisters in the development of the picture.

These details may appear somwhat troublesome, but they are not really so in practice; though it must be admitted that a certain amount of care and judgment is required to carry them out successfully.

In the demonstration referred to the print was developed on a glass plate as a transparency, and afterwards intensified with the permanganate of potash. It was then slightly retouched, and afterwards employed to make a new negative, from which impressions could be produced with one printing. Sometimes, we are informed, M. Lambert proceeded somewhat differently and made the enlargement direct from the small negative, the full size, as a transparency. He then worked this up, masked and double-printed it as just described, producing a negative which in turn was also worked up, if necessary. By this means much time and trouble was saved in obtaining the final printing negative.

We intend to continue the subject of combination printing next week, and give some practical hints on the production of combination negatives by other methods.

ENGLISH AND FRENCH WEIGHTS AND MEASURES.

Photography is cosmopolitan enough to render the abstraction and compilation of foreign formulæ in English journals a matter of commen occurrence—a fact which, in combination with the general tendency among scientific men to adopt the French or metrical system to express the results of their investigations, causes an acquaintance with the relative values of the two systems to become an actual necessity if a photographer is to read the literature of his profession with profit or understanding. This is no place to discuss the merits of the various systems, we must take the facts as we find them; otherwise it would be very easy to show that the metrical system has not the basis of exactitude that was once claimed for it, nor is it, in many respects, as useful as our own system of weights and measures which it is now the fashion so much to decry.

So far, however, is such knowledge of the equivalent values of the terms employed in the two systems a common possession—whether among photographers or other technical workers—that if all formulæ published in this country were to be couched in the metrical system they would find few readers who could readily understand them. Alterations in weights and measures, above almost any innovations, are difficult to establish; but, apart from this, the very elaborate and difficultly-worked English equivalents of French measures hitherto given by authority have much to answer for in this direction, and any simplification of calculation that shall give results which may be considered scientifically exact will be thankfully received by the general public.

With such thoughts in mind we welcome a most excellent move in this direction recently made by Dr. G. Johnstone Stoney, F.R.S. He has proposed a series of equivalents which, if employed, would greatly facilitate calculations; and they differ in a very slight degree only from the present accepted measurements and weighings. The actual comparison of standards is a very interesting series of observations, but cannot here be touched upon, and though of late years older processes have been much improved, still, for all practical purposes, Dr. Stoney's figures may well be accepted for operations in photography as in other sciences. There is nothing finite in the results of calculations and measurements of equivalents; a British act of parliament exists in which a legalised value is given that does not accord with the equivalents now accepted by scientific men and Dr. Stoney's figures. One of the earlier accepted equivalents was Captain Clarke's determination of the yard in metrical measure, and this was followed by that made for the Ordnance Survey by Captain Kater. The two measurements were not exactly alike, and the difference between them is greater than that between the present (Dr. Stoney's) suggested, easily-calculated equivalents and those of Captain Kater.

The French system, as many of our readers are aware, is based on a measurement of a certain portion of the earth's surface—a fourth part of a terrestrial meridian, the ten-millionth part of which was adopted as a unit and termed "a metre." A cube having its sides one-tenth part of a metre in length was adopted as a unit of capacity, and called "a litre." For a unit of weight a litre measure of distilled water was taken, and called a "kilogramme," and its thousandth part adopted as the weight unit, under the denomination of a "gramme." Multiples of these, reckoning by ten times, were called "deca," "hecto," "kilo," and smaller divisions by tenths, "deci," "centi," and "milli." The system is very simple, and the units are easily interchangable; but, as we have said, they are less convenient in some respects than our own.

Turning, now, to Dr. Stoney's equivalents: he would take the yard as 914·4 millimetres, which would leave an outstanding error not appreciable in work that might be called really scientific—a difference from present accepted measurements less than would be caused by the lengthening or expansion by heat of an iron yard measure when raised one degree in temperature. Next, for the equivalent of a pound, he suggests—the pound = 453·6 grammes. This differs from the most elaborate equivalent yet made—namely, Professor Miller's—by only a-quarter of a grain in a kilogramme, the small importance of which may be judged of when it is stated that the difference shown between weighing a litre of water in air and in vacuo would be seventy times as much. For the gallon he suggests 4544 cubic centimetres as an equivalent, which would not be one drop wrong in a pint.

If, now, these equivalents be accepted, the following tables will follow from them, and will be found far easier to remember and use than the usual elaborate equivalents taken to many decimal places usually employed:—

Table I.—Measure of Length.

The yard	=	914·4 millimetres.
The foot.............................	,,	304·8 ,,
The inch	,,	25·4 ,,

Table II.—Weights.

The pound............................	=	453·6 grammes.
The half-pound......................	,,	226·8 ,,
The quarter-pound	,,	113·4 ,,
The ounce	,,	28·35 ,,
The grain	,,	·0648 gramme.

("This last gives the gramme = 15·4321 grains, a number which it is singularly easy to recollect.")

Table III.—Measure of Capacity.

The gallon	=	4544 cubic centimetres.
The quart....................	,,	1136 ,,
The pint	,,	568 ,,
The half-pint	,,	284 ,,
The noggin	,,	142 ,,
The fluid ounce	,,	28·4 ,,

It is further stated that the utmost limits of accuracy may be obtained by making the following corrections in these tables:—

Table I.—	Substract one in every hundred thousand.	
,, II.—	,, ,, sixty	,,
,, III.—	,, ,, ten	,,

Measurements of temperature remain yet to be discussed. All our readers are aware that the accepted scale of this country calls the freezing point 32° and the boiling point 212°, while the French or centigrade scale gives 0 and 100 respectively to these points. For a very rough estimate, Fahrenheit degrees may readily be translated to centigrade by subtracting 32 and doubling the remainder. Complete exactitude will be found if this result be diminished by subtracting its tenth part. This rule will in practice be more readily performed mentally than the common one of subtracting 32, then multiplying the remainder by 18, and dividing by 10. This rule was communicated by a correspondent, but it is so simple that it may likely enough be found elsewhere.

We may conclude by giving another equally simple, rough rule (which also we have never seen in print, though it is equally probable it may be so found) that we employ where French prices have to be converted into English. It is simply to multiply the price of francs by four, and then take off the two right-hand figures. Those remaining represent English pounds sterling.

The subject we have thus dwelt upon represents a considerable array of figures; but, in view of the importance of being able to readily translate English to French quantities, we think their greatly increased simplicity will commend them to our readers.

Mr. J. P. Mayall, of Park-lane studio, has had the honour of photographing Mr. Gladstone, in his sitting-room at Hawarden, for the series of "Artists' Homes" now in preparation by Messrs. Sampson Low, Marston, and Co. The right honourable gentleman, we presume, finds his way into the series by virtue of his Professorship of Ancient History to the Royal Academy.

The engravings in the folio edition (Venice, 1488) of *I Triomphi*, of Petrarch, recently purchased by the British Museum from the Sunderland collection, have been reproduced by photogravure, together with three others, forming the illustrations to *Il libro del Monto Sancto de Dio*, by Bettini, 1477, the engravings being by Botticelli, and also the nineteen illustrations of the *Divina Commedi*. The plates are now ready for delivery to the subscribers.

The French Institute has also published a photographic *facsimile* of the Leonardo da Vinci manuscripts in the library of the Institute, the work being edited by M. Charles Ravaisson-Mollien.

When distilled water is not available it is often recommended to use rain water, and for certain purposes it is an efficient substitute; but for many operations it is inapplicable on account of the ammonia it usually contains, which would be quite fatal to some experiments, and as the amount present is not a constant quantity no standard allowance can be made for it to neutralise its effects. According to Herr Hozeau the principal agents which increase or diminish its amount are light and heat. In July he was not able to detect even a trace of it in rain water, and he also noticed that water exposed to the action of sunlight for a long time lost a large part of its ammonia. The amount of rainfall also influenced the quantity present, which, as might be inferred, was in inverse proportion to the amount of rainfall.

M. Becquerel, whose researches in the spectrum by the aid of phosphorescent tablets we alluded to last week, has noted that the infra-red spectrum can, with an ordinary sprectroscope, be examined down to about wave-length 8,000 if the light be concentrated upon the slit, and the more luminous rays filtered out by a solution of iodine in bisulphide of carbon.

In addition to our remarks in a recent number upon the separation of the haloids, we may here note still another process lately published in the *Chemiker Zeitung*, by A. Cavazzi, for the separation of iodine, which is as simple as useful. Ferric chloride, it is known, will liberate iodine and bromine when present in a mixture of the three haloids, and Herr Cavazzi finds that ferric sulphate will separate the iodine alone. It must be free from acid for the purpose, and to make it so he heats the salt to redness. It is then rather insoluble; but by adding from five to ten per cent. of ferrous sulphate the solubility is so increased as to enable water to take up a twelfth of its weight. When a mixture of iodine, bromine, and chlorine is boiled in this solution the iodine is driven out. It can be absorbed by potash, and the iodate thus formed reduced to iodide, which he is enabled to do by the hydrogen evolved by adding aluminium. Precipitation by silver nitrate in the usual way enables the amount to be estimated with exactitude.

It is not often that a photographer requires to use a thermometer with such attention to accurate reading as to note tenths of a degree, though our own experience in pyroxyline enables us to say that a very marked difference in the properties of the cotton is produced by a variation in the temperature of the mixed acids of a single degree. Still it is worth noting that an error amounting to several tenths of a degree may take place within half-an-hour when the stem of the thermometer is heated to 250°.

It is not generally known that any one possessing a thermometer of good quality which he desires to have tested can, for a very small fee, get a thoroughly complete examination of its powers, together with a written character detailing its defects, by sending it to Kew. There are few thermometers which are perfect in their readings at all temperatures. The makers of those of the best class, intended for experimental research, take great pains with each instrument; but there is generally some residual error left, and of this the authorities at Kew will make note. There are many interesting points about the performance of thermometers, under certain conditions, that cannot well be treated in a short note, but with which we may, if we have space, deal more fully on another occasion.

As an example of the power of the emulsion filter, described some few months back by Mr. C. Beckett Lloyd, a recent experience may be quoted, which will also serve as a warning to others. A thick solution of pigmented gelatine was being filtered through a plug of tow, the cork at all the "joints" having been "luted" with a little of the gelatine to make the whole perfectly air-tight and to secure the full advantage of the exhaust. All went well, though slowly, for a short time, until the tow became clogged with the thick, viscid gelatine, when, under the increasing pressure from without as the filter cooled, the stout glass flask collapsed with a loud report. Moral: for very viscous solutions employ stronger vessels.

Glass is generally looked upon as a most inert and repellent body to the action of almost all chemicals; but, as we have before shown, it is capable of being dissolved on its surface by pure water even, while anyone who keeps a store of chemicals in his laboratory knows too well, by the fastening of stoppers, not to speak of the staining or visible corrosion of their interiors, that many liquids interfere with the integrity of their vitreous receptacles. Professor R. Bunsen has lately been investigating the condensations of carbonic acid on the smooth surface of glass, which he states goes on for years notwithstanding continued changes of density and pressure. He asserts that in three years' time each square centimetre absorbs, at standard pressure and temperature, 5·135 cubic centimetres of the gas, about two-thirds of this amount being absorbed the first year. No wonder that photographers at times experience irregularities in the adhesion of their coatings of collodion and of emulsion when it is shown how porous glass usually is even to a gas.

DARK-ROOM ILLUMINATION.

The many letters of inquiry that I have received on the subject of the particular method of lighting photographic dark rooms, to which I have recently called attention, and the fact that even those who have written in the photographic journals upon the matter have, evidently, not had in their minds some of the points which I mentioned when exhibiting the results of my experiments at meetings of the Photographic Society of Great Britain and at the London and Provincial Photographic Association, induce me to think that a few collected remarks will not, at the present time, be out of place.

The proposition of the proper light for the dark room has often been put in this way—"*Get a safe light and use plenty of it.*" But what is a safe light? Presumably the expression means a light that is without chemical action upon a sensitive film. I have yet to learn that any such light exists. The proper way of putting the problem appears to me to be this:—*What is that light which, when of a certain intensity judged sufficient for working by, has the least effect upon the sensitive plate?*

In the early days of photography certain different appearances upon bromide and iodide of silver when submitted to the spectrum were thought to indicate great relative differences of sensibility in these salts to light coming from objects of various colours compared with their sensibility to white light, and a theory was in consequence formed that bromide of silver was sensitive especially to yellow and green light. Sir John W. Herschel was one of those who first promulgated this theory, and his authority has been used in support of it; but I am happy to find that he afterwards saw reason to alter his views.

The theory has, however, been kept up and insisted upon so long that photographers have accepted it as a matter of course, and when bromide of silver first came into general use in the form of collodion emulsion it was found that the plates, although slower in the camera than the iodide bath plates, yet fogged in the yellow light of the dark room. This fact was thought to be accounted for by the superior sensibility to yellow light inherent in bromide of silver, and the use of ruby glass, admitting very little light to the eye, was insisted upon.

Another explanation may be found in the fact of the much longer exposure to the light, whatever it may be, of the dark room, to which bromide emulsion plates were subjected. With the iodide plate the only exposure up to the moment of developing was in the passage from the bath to the dark slide. With the bromide emulsion, on the other hand, there were the operations of preparing the emulsion, washing it, coating the plate (and each time a plate was coated some emulsion was poured back after having been exposed to the light), drying, and storing. The development of the bromide plate, too, sometimes required minutes when the iodide had seconds, and there was the fact that the bath plate became less sensitive as development went on—a condition which does not appear to exist with bromide emulsion plates. All this exposure to the light of the dark room is quite sufficient (especially now that bromide plates are made so much more sensitive altogether) to account for the different intensity or quantity of light permissible, when working gelatino-bromide plates as compared with iodide bath ones.

Another instance of the effect which the persistent re-assertion of this idea of the greatly different colour-sensitiveness of iodide and bromide of silver had upon the photographic mind, may be found in the literature of photography at the time when rapid gelatine plates first came into ordinary studio use. This was in the winter of 1878, and it was then supposed by some writers that the superior sensitiveness of gelatine plates was due to their special sensibility to the yellowish light of winter, and that, when the more powerful light of spring and summer came round again, there would be found no difference, or but a very slight one between the speed of gelatino-bromide and collodio-iodide plates. Experience, however, showed that the relationship of sensitiveness was not altered to any extent that could be proved. The sheet of ribbons of various colours shown by Mr. J. R. Sawyer at the last May meeting of the Photographic Society of Great Britain, and the photographs from them, in which it was seen that the ordinary collodion and gelatine plates gave the whole set of colours in identically the same relationship, should either set the question at rest or lay upon those who still assert that the great difference of colour-sensitiveness exists in the two processes the onus of proving the truth of their assertions.

Ruby glass will certainly cut off more of the chemical action of light than yellow glass; but, then, it will cut off at the same time *very* much more of the luminosity to the eye by means of which we perform the operations of the dark room. To make the comparison usefully we should, either by repeated screens of yellow, by lowering the source of light, or by some means at all events, reduce the intensity and the quantity of the yellow light until it reaches the same amount of brightness of illumination to the eye that we have with the ruby light, and then see which has the most chemical effect upon the plate.

I am pleased to see, by an article in a recent issue of The British Journal of Photography, that Mr. W. H. Harrison has—although from a former article he appeared not favourably disposed to the green and yellow combination—come by the test of direct experiment to speak very decidedly in its favour. I may say that I arrived at my results originally in a similar manner to that in which Mr. Harrison tested them; that is, by the exposure of a plate to openings covered by different combinations of coloured glass and paper, forming what he describes as a polychromatic negative. Mr. Harrison has, however, overlooked the fact that, at the meetings of the societies where I showed my lantern, one side was glazed with ruby flashed upon orange pot metal, and another side with ruby glass and one thickness of the same paper that was used with the green glass. With the green glass there were two thicknesses of yellow paper, because the green allowed so much more visual light to pass than the ruby that even with the extra thickness of paper that side of the lantern was considered to afford the best light by which to work. The remaining side only was glazed with the two thicknesses of red glass. He says:—"Had Mr. Debenham used two kinds of red, or ruby glass superimposed on orange, it is probable that the actinic rays would be more powerfully cut off than by his greyish-green, although the latter is more valuable for ordinary practical purposes."

It will be seen that what I am assumed not to have done is exactly what I did, and I showed the plates which had been exposed to these ruby-orange and ruby-yellow lights, which plates were described as showing an image of intermediate strength between the trace obtained on the green-yellow side and the strong image of the plate exposed to the light through the two ruby glasses. From being thought not to have tried these combinations, Mr. Harrison, although approving strongly of the light I advocate, calls my "comparative experiment an unfair and inconclusive one." The expressions "ruby-orange," "ruby-yellow," &c., are of course used, not to describe the apparent colour of the light, but to indicate the colours of the media through which it has passed.

The coloured tissue papers mentioned by Mr. Harrison may, indeed evidently have, in his case answered very well for lanterns when the source of light is not a powerful one; but I cannot approve of a single thickness of any medium which has holes or interstices. So far as that medium is concerned there are places in which light passes unaltered. The same remark applies with greater force to a single thickness of any textile fabric, such as twill or tammy.

The number of thicknesses of glass and paper required must depend upon the strength of the light and the sensitiveness of the plate. For daylight I use a fixed frame, containing one thickness of a pale green glass and two thicknesses in winter or three in summer of the deep yellow paper, kept in place and free from splashes by a sheet of ordinary glass. In front of this is a movable screen similarly covered. For lanterns a single thickness of glass and two of paper suffice, although for the coating room I use an extra thickness of the paper. One friend uses a deeper glass, and then one thickness suffices him with two of paper. To any readers who wish to be relieved from the fiery glare, and who would like to see patterns of the glass and paper that have been successful with me, I shall, on receipt of directed envelope, be happy to post small samples. A letter addressed to my name, Haverstock Hill, London, will find me.

It is sometimes said that it does not follow that, because a certain light is best for developing, it is also the best for preparing and coating the plates. It seems to me that if with a certain colour of light there is less chemical action for a given amount of luminosity to the eye, that colour is best for all purposes—preparing and coating more especially; and I am writing particularly with the desire of inducing a change in the workrooms of the dry-plate makers, where amongst the many employed there can be no reasonable doubt that the eyesight of some is being ruined. And what a prospect for the worker when that takes place! For my own part, I certainly think that my plates are clearer since I have abandoned the ruby glass and orange paper that I formerly used in the coating-room as elsewhere.

There is one other point to mention. I am at a loss to know what colour to call the light. The colour to the eye of the combination of glass and paper that I use is not at all green. Yellow glasses or papers when superimposed in several layers appear orange, and sometimes almost red. The green glass seems to have the effect of cutting off some of the actinic rays and of doing away with the hot orange colour of the light, and making it more pleasant without much lowering its illuminating power.

W. E. Debenham.

INTENSIFICATION OF GELATINE NEGATIVES WITH SILVER.

That not a few of the votaries of the art would forsake mercurial intensification for silver and iron or other permanent re-development, were they assured of the absence of abnormal or other stains, may be taken for granted. With the permission of the Editors I shall lay before the readers of the Journal a method of intensifying gelatine negatives with silver and iron which has rendered good service since the summer of 1880. I mention the date simply to show that it has stood the test of experience.

The chemicals necessary are identical with those used with wet collodion, with the exception of the chloro-iodo bath, which apparently decomposes the active principle or constituent in the gelatine that causes the well-known pink fog. Neither iodine nor chloride of sodium by itself will prevent the pink stain, but a combination of both as prescribed. The image is, probably, converted into iodide of silver, which in turn gives place, to some extent, to the excess of chloride, forming both iodide and chloride of silver in the film, and during the decomposition the fog-producer is destroyed or rendered harmless. At all events, the negative is very readily and successfully intensified after its immersion in the bath.

The following are the requisite solutions:—A, saturated solution of common salt; B, ruby solution of iodine in iodide of potassium; C, ten-grain solution of protosulphate of iron; D, fifteen-grain solution of nitrate of silver; E, a very weak solution of cyanide of potassium.

When the crystals in solution D are dissolved a few drops of a saturated solution of carbonate of soda should be added, and the bottle placed in the light until clear. The silver should then be filtered and acidified with acetic acid (eschew nitric) enough to turn litmus paper red. To solution C half-an-ounce of glacial acetic acid must be added to every fifteen ounces of water.

Test a mixture of C and D thus:—Pour into a developing cup half an ounce of C and add (say) half-a-drachm of D. If the combination turn muddy in less than five minutes, add more acetic acid to the stock bottle C until it remains clear when mixed with the silver solution for the specified time.

To intensify the negative:—It is premised that the negative has been "alumed" and washed thoroughly to free it from the fixing agent. If the film be tender it is best, in the first place, to dry it. Now pour into a clean measure sufficient of A to cover the plate; then add a few drops of B until the colour of amber be attained. Immediately place the negative in a clean tray and pour over it the chloro-iodo solution. Leave the plate in this bath for four or five minutes—the thicker the film the longer it should remain—then well wash it under the tap. As vegetable and other extraneous substances from the washing water often adhere tenaciously to the surface of the film, thereby causing irregular markings, at this stage any such should be gently removed by a tuft of cotton wool dipped in water.

The next operation must be done in the dark room—one in which wet collodion can be worked—or by candle or gaslight. To proceed: into a developing cup shake a few drops of D, and add (say) for a half-plate almost half-an-ounce of C. Flow this on the negative and let it remain for three or four minutes—not longer—gently rocking the plate the while; then quickly place it under the tap until all greasy lines have disappeared. It will now be seen that a considerable increase of density is the result. One operation generally suffices; but if the image be still too thin clean out the cup and repeat the dose. The plate will be thin, indeed, if it require a third application. After a good wash place the negative in solution E for one or two minutes, when it may be examined in daylight. Well wash again, then dry, and varnish.

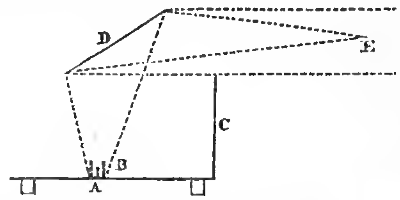
If ordinary precautions be taken with the above method there will be little fear of red fog; but if, from inadvertence or other cause, it should appear, immediately immerse the negative in a fresh solution of A and B. It has the valuable property to a great degree of clearing off the stain. Should the fog be deep and obstinate, place *out of doors* the plate in a solution of potassium sulphide, when it (the stain) will gradually vanish. This treatment intensifies the negative. It simply requires to be well washed in running water, dried, and varnished. A. DONALD.

AN IMPROVED DARK-ROOM LAMP.

IN Mr. G. D. Macdougald's description of his method of dark-room illumination, in your issue of the 4th instant, he states that it involves exactly the same principles as that of the lamp I described in the previous number. He evidently quite misunderstands the theory on which my lamp is based. We know that every opaque surface reflects more or less white light (even a surface such as velvet at certain angles will reflect almost pure white light); but if over this opaque surface we can paint a transparent colour (or, as artists call it, a "glazing" colour) the light when reflected from the opaque surface will have to *pass twice through the transparent colour*, and the colour of the reflected light will consist of a combination of that of the light and of the opaque and transparent mediums.

I therefore painted the interior of my lamp white to reflect as much light as possible. Over this I painted a non-actinic transparent colour, for this reason: as the light would have to pass twice through the colour, I thought the latter would absorb the actinic power of the light in its passage in the same way as ruby glass does by transmitted light, and the result showed that the supposition was correct. I wish I had explained this more fully in my article, but I thought it was hardly necessary.

In Mr. Macdougald's arrangement, from the top of the tube surrounding his gaslight or candle to the ceiling there is a beam of *white light* passing upwards through the room. He does not say the distance from the light to the ceiling, and this is a most important point. If the candle were placed on a table and the ceiling were five or six feet above, the amount of light reflected on to the table from a *dark* orange matt surface on the ceiling must be nearly or quite *nil;* and I think he would find it so if he were to arrange his light in this way:—



A, Table. B, Candle in tube. C, Shield to cut off white light. D Reflector—a dark orange matt surface. E, Point where the plate is developed.

Five feet to be allowed from the candle to the centre of the reflector, and the same distance from the reflector to the point E.

I have no doubt that the light Mr. Macdougald works by is the weakened white light reflected from the particles of dust, &c., in the air as the light passes from the candle to the ceiling, and not the orange light reflected from the ceiling. If this candle were close to the ceiling, of course the reflected light would be more powerful. I note that Mr. Macdougald does not say how he examines his plates by transmitted light to see the density.

The reason I made my lamp square was to absorb every particle of white light possible. In the first place, the whole of the white light is contained within the lamp, and none is allowed to pass into the room; then the light from the sides and top is reflected within the lamp, and the white light is thus rendered more non-actinic by the reflected coloured light mixed with it, which would give a colour to any particles of dust, &c., that might have reflected white light into the room.

I quite agree with Mr. Macdougald that the more extended the reflecting surface is—that is, the further from the light, and in consequence the less light it would have to reflect—the safer it would be for photographic purposes, provided the white light is shaded from the plate in its passage to the reflecting surface. The reason I made my lamp so small was to have as little white light within it as possible.

While on the subject of my lamp I may give the result of further experiments made by Mr. A. L. Henderson and myself. The light from a paraffine lamp covered with deep ruby glass, then passing through a bath containing a solution of bichromate of potassium, then through a bath of solution of quinine, will fog a very rapid plate in two or three seconds; whereas with a plate three and a-quarter inches wide put close to my lamp (painted with raw sienna, as I described) for thirty seconds, the part nearest to the lamp gave a slight deposit, but the film on the part farthest off did not show the slightest trace. The reason of this is that in the case of transmitted light the bulk of the actinic power comes from the one point—namely, the flame—direct to the plate, whereas with my lamp the actinic power is first dispersed all over the interior of the lamp. In the one case we have a weak light concentrated on one spot, and all around is perfect darkness; in the other a flood of light (in comparison) of a very light yellow tint. As Mr. Henderson described it, "the light was grand!"

I tried the effect of Mr. Debenham's proposal of painting the interior of the lamp chrome yellow (matt surface) and putting a piece of green cathedral glass in front of the lamp. I found that it gave a very luminous light; but I could not try the photometric value of the lights, as I had painted the yellow over the raw sienna. In each case I was very much struck with the rapid falling-off of the actinic power of the light the farther the plate was placed from the lamp compared to the loss of luminous power. For instance: at fifteen inches from the light (with yellow and green glass) on a plate of about fifty times rapidity we got a faint deposit in one minute, but at twenty-seven inches we could get no deposit in fifteen minutes. As we got no deposit in half-a-minute about five inches from the lamp (painted raw sienna, without any glass) I have no doubt that it would be equally safe, if not safer, at the same distance. As there is ample light to coat plates at two or three yards' distance from the lamp, it must be quite safe for all practical purposes both for coating and developing plates. I tried the effect of putting orange instead of green glass in front of the lamp, the plate being put twenty-seven inches from the light and the orange and green glass together, with the plate fifteen inches off, the exposure in each case being fifteen minutes. In neither case could I get a deposit.

As I stated in the postscript to my article, the plate that I exposed for an hour and a-half close to the lamp was much slower than I thought. Mr. Henderson found that they only gave 9 on

Warnecke's sensitometer. I also developed it with the same amount of bromide as I used for ordinary development. When Mr. Henderson tried the lamp he got a greater deposit on his plates than I did, after allowing for the relative rapidity of the different plates; but in one case he had intensified the plate to such an extent that he got a greater deposit on it in ten minutes than he did on another plate of about sixty times the rapidity in two minutes. Of course intensification was very useful in proving that the light had really acted on the film, but had not much bearing on ordinary development.

On the subject of reflection from matt surfaces Mr. Macdougald will note that I only proposed to use double reflection for daylight. I am quite aware that a very great deal depends on the nature of the surface employed; indeed, it was in consequence of noticing the great difference of the same colours on different surfaces that led me to take up the question at first. In the autumn of 1881 I tried my first experiments on the subject. I got some buttons covered with different-coloured dress material, the roughness, &c., of the surface being, as near as I could tell, the same, and on photographing them I was very much surprised at the results, as the effect on the film was so very different to what I expected. I spoke to several practical photographers on the subject, and pointed out to them how important the knowledge of these tone equivalents of different colours would be to them in obtaining a proper balance of light and shade in their pictures, and the necessity of making the tint given on the film from the sitter's dress the starting-point for the arrangement of suitable accessories and background. They thought it was very interesting to those who cared about such things, but they preferred to go on their old rule-of-thumb method. In last year's *Year Book* I raised the question in its bearings in relation to "the addition of iodide to a gelatine bromide film;" but, with that exception, until I took up the subject of the lamp I had not thought anything further of the matter.

I wish to say that in my experiments with the lamp I took for granted that the power of light reflected from a blue-painted surface would have the same relative power on a sensitive film compared with a yellow-painted surface as the blue-covered button did to the yellow; and if two surfaces—one rough and one smooth—were painted with the same colour (say blue), when photographed the *relative difference* in the deposit on the film in the two cases would be the same as if the two surfaces were painted yellow or any other colour, so that I did not try with a painted surface anything I had already tried with the covered buttons.

Mr. Macdougald proposes that I should try experiments as to the photometric values of the different colours. Now this was quite a secondary question to settle in connection with my lamp. It would have been useful in comparing a raw sienna transparent surface with Mr. Debenham's proposal of an opaque yellow surface and green glass. What I wanted to find out was from what surface has reflected light the least power on a sensitive film *placed close to the lamp*, and which would give at the same time the most pleasant light to the sight. After finding that out—by putting some transmitting medium in front of the lamp, such as coloured glass—I could easily reduce the actinic power of the light; but I wanted to do away with transmitted light altogether.

And, now, as to the real or absolute photometric value of the light reflected from different coloured surfaces: of course when the spectrum is thrown on a sensitive film and thus photographed the photometric value of the different colours are not equal, and the density on the film does not at all correspond to the intensity of the light. By-the-bye, has anyone thrown the spectrum on a white surface and then photographed it by reflected light in the camera? This would be a most interesting experiment, and would have a most important bearing on the subject of reflected light.

As near as I can remember the colours of the various buttons which I used were about the same as a painted representation of the spectrum. I did not try the whole of the colours of the spectrum, but I tried some of the colours of the secondary and tertiary scales. If Mr. Macdougald will repeat my experiment with the buttons or with pieces of coloured ribbon, and have among others pieces of blue, yellow, orange, and red, as near the colours of the spectrum as possible, I have no doubt he will find that what I stated in my article was correct. I remember I thought at the time that the reason of the orange giving nearly as dense a deposit as the blue was on account of its being more luminous; but I could not understand why the yellow, which was even more luminous than the orange, acted so differently.

About a month ago I commenced the collection of different materials of the same colours and tints, the only difference being the roughness, &c., in the nature of the materials. I have already obtained from a friend several hundred examples, and by the time the days get long enough to allow me to get my camera out for experimental work after business hours, I hope to have a large collection, photographs of which I think will be very interesting.

I have just seen Mr. W. H. Harrison's remarks on my lamp, in a recent issue. He seems, too, not to have noticed the difference between light reflected from an opaque surface and light twice transmitted through a transparent medium. There is another point he raises in connection with the subject, namely, the action of actinic force with regard to colour; but this article is already so long that I must leave that subject for another communication.

HERBERT S. STARNES.

LANDSCAPE BACKGROUNDS IN FIGURE SUBJECTS.

THE reference recently made by Mr. Edward Dunmore, at a meeting of the Photographic Club, to a now nearly-forgotten but ever-excellent method of printing landscape backgrounds in portraits induces me to add to what has already been said concerning it, with a view to keeping it prominently before your readers.

This process, as originally described, consists in printing the portrait to the full depth required, the background being presumed to be sufficiently light to enable other subjects to be photographed thereon, but in, of course, a more subdued tone. When it is removed from the printing-frame a camel's-hair brush charged with gamboge mixed up with water is passed over the portrait, care being taken that, on the one hand, the whites of the figure are covered, and, on the other, that the entire background is left untouched. The print thus masked is now exposed to light under a landscape negative, after which the gamboge is removed by placing the print in a vessel of water, the toning and fixing then being effected in the usual manner.

Recollecting that I had heard complaints concerning the ill effects experienced by wetting certain parts of the print, I set to work to discover in what manner this might be obviated. It appeared evident that a thin, transparent pellicle—if superposed upon the print, and the figure then carefully stopped out upon *it*, instead of upon the print itself—would answer every purpose, without being liable to the objection used against the system of working with aqueous colour upon the silvered paper.

In carrying out the idea here indicated I tried various thin pellicles, the first to be pressed into this service being gelatine as supplied by artists' colourmen and stationers who supply the requirements of confectioners. A thin sheet of this gelatine, when superposed on the portrait, lies in such close adherence that it is quite easy to make the most delicate traceries round the figure. As the readiest means of doing so I adopted a pigment formed by rubbing down of China ink in common writing ink, and applied it round the margins by means of an ordinary steel pen having a turned-back point like those designated "Waverley." After the marginal outline was formed the body of the mask was filled in by means of a brush.

This method answers so well that I can very strongly recommend it. All that is necessary, when about to print a background, is to lay the mask down upon the previously-printed portrait, adjust it to the margin of the figure, and take precautions to ensure its not being removed when placed in the printing-frame which contains the landscape negative. By adopting this method the one mask answers for every print that may be required from the same negative, saving both the trouble of having to work upon each print with the gamboge and the difficulty and annoyance arising from the application of wet pigment upon an untoned print. A solution of india-rubber applied to the margin of the mask forms a very good cement which, while keeping it attached to the negative, still permits it to be readily moved should the adjustment not have been perfect.

I have also, with an equal degree of success, made use of ordinary tracing-paper in the formation of the mask. This possesses the advantage of being rather more easily worked upon than gelatine by the pen or brush with which the mask is made. At first sight an objection would be urged against this medium on the ground of its lacking perfect transparence; but neither is this nor any further objection arising from its thickness of any validity. It should be borne in mind that, as the background must be in subordination to the figure, it is not only unnecessary, but it is undesirable, that the landscape should be as sharp as it is capable of being rendered by the negative; hence the interposition of a thin sheet of translucent paper proves rather advantageous than otherwise. Indeed, to such an extent may the negative be separated from the print, that I have made the mask upon a thick sheet of wove paper rendered translucent by an alcoholic solution of castor oil, and the softness conferred on the background by this imparted quite a charm to the finished picture. OMEGA.

THE PAMPHENGOS.

As regards the desirability of having even an approach to a substitute for the lime light, possessing a degree of strength or intensity sufficient for a second-rate lantern exhibition, no person will express a doubt; but as respects a hope or expectation of oil illumination being ever brought to such a state of perfection as to supersede oxyhydrogen for any purpose whatever for which it is now being employed, experts will probably shake their heads.

When we read of that skilful and experienced lantern exhibitor, Mr. B. J. Malden, giving his endorsement to an allegation as to a certain quadruplex oil burner equalling many exhibitions with the oxyhydrogen lime light which he had seen, we did not attach to the statement the importance we should have done, knowing that some lime-light exhibitions were not unfrequently poor enough; but when this was still further confirmed by Mr. Lewis Wright, the author of a meritorious treatise on *Light*, who stated that not only had he seen a well-lighted twelve-foot disc produced, but that the lamp possessed sufficient power, as tested by himself, for projecting polariscope objects in a manner sufficiently brilliant for class demonstration, on a disc five feet in diameter, we felt that an inquiry might fittingly be instituted into this matter, because, as everyone familiar with the phenomena of polarisation by the lantern is well aware, much less than half of the emitted ray only reaches the screen.

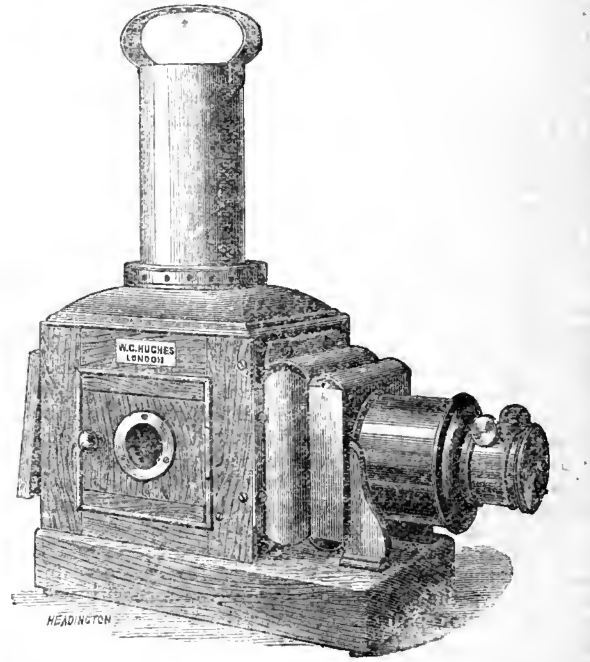
The light by which such good things are effected rejoices in a north-eastern origin and a Greek designation, namely, the "Pamphengos," of Mr. W. C. Hughes, Hackney and Kingsland-road, and by it is purported to be solved the difficulty of securing a higher class of combustion than heretofore obtained. Believing that the best way to test the performance of any special mode of illumination is to do so when the demonstration is made by its maker, we accordingly called at the factory (Brewster House, Mortimer-road, N.) and requested permission to witness the capabilities of the Pamphengos—a request with which Mr. Hughes promptly and courteously complied.

While an assistant was being despatched upstairs to the exhibition room to "light up," we took occasion to cast a glance round the lantern department. A specialist in these instruments, Mr. Hughes keeps here nothing but lanterns and their appliances. The show-cases were amply supplied with condensers of every size and degree of curvature, both mounted and unmounted. Here, too, were displayed innumerable achromatic objectives, which differed from the ordinary French portrait lens in some respects—such as the greater diameter of the lenses for a given focus; the more substantial workmanship, especially in the racking; and the double end to the pinion, by which milled heads projected at both sides for facilitating focussing from either side of the lantern, which is a source of great convenience. Polariscopes, lantern microscopes, lime-light burners of the various sorts now in use, dissolving taps, and other lantern appliances were also here in rich profusion. These several items of brasswork were finished in a most excellent and substantial style—much better, indeed, than one usually expects to find in lantern fittings. Arranged on shelves we saw quite a variety of lanterns in every style, and at prices ranging from £50 downwards. But a lantern of this character is a work of engineering art, having a triple optical system controlled by dissolving taps so perfectly as to enable the very refinement of dissolving views and mechanical effects being indulged in. As we looked over the great display we concluded that the powers of the lantern are at length recognised, and that it has now taken its position as an important social teacher and demonstrator in the arts and sciences, as well as fulfilling its original *rôle* as the ever-popular amuser of the domestic circle.

We had only time to take a hurried glance round the well-decorated walls of a large show-room adjoining, in which were displayed many hundreds of choice slides of recent outcome—all of them prettily coloured, some of them elaborately so—when the word was passed for us to proceed upstairs to the demonstrating hall, in which the Pamphengos, now lighted up, was in waiting to receive us.

There was no doubt at all of its success. "Seeing," in such a case, "was believing;" and there before us on a disc, which measured eleven feet six inches in diameter, was projected a photograph from nature, beautifully lighted and sharp all over. The conclusion at which we arrived, after having seen upwards of a dozen slides passed in review upon the screen, was that undoubtedly it was the best light from oil that we had ever seen, and that in innumerable cases it might be made most fittingly to do duty for the lime light. A few subsequent experiments satisfied us of the capability of the light for showing microscopic objects of the low-power class, prepared for exhibition by the oxyhydrogen light, while with the polariscope it far surpassed our expectations.

With respect to the instrument itself the annexed diagram affords an accurate idea of its external form, which is certainly



very elegant. The burner is composed of four wicks placed parallel with each other and axially in the lantern. They are controlled by pinions projecting behind. The air supply is adjusted in such a manner as to cause the flames from these to be deflected towards the centre, thus forming a rather small flame of exceeding great intensity. The chimney is of metal and somewhat tall, so as to ensure perfect combustion; while the portion immediately surrounding the flame is formed of metal, having a large aperture, both in front and behind, to permit the passage of the light to the condensers on the one hand, and the reflector on the other. These apertures are protected by small curved panes of glass, annealed so as not to be liable to breakage by heat.

One of the important conditions of success lies in the lighting of the lamp in the proper manner. Mr. Hughes recommends that it be done so slowly as to occupy about five minutes before the full effect is obtained. This care at the preliminary stage is the key to success in securing intensity and purity of light. The lamp is evidently constructed with thoughtful attention and with a due regard to the admission not only of air in the requisite quantity, but also, as respects its direction, so as to impinge properly upon the flame. The result of such care is a light both pure and intense, and one well adapted for showing colours and photographs on an enlarged scale.

The condensers are formed of two plano-convex lenses four inches in diameter, with perforations in the mount to prevent the condensation of moisture on the inside surfaces. The objective is, as previously hinted, of rather larger diameter than the French lenses commonly employed, and it defines well to the margin. Altogether we are justified in saying that the Pamphengos is decidedly a step in advance in the applied science of optical projection.

PRINTING.*

I STRONGLY advocate the adoption of ammonia fuming by all those engaged in printing from gelatine dry plates, being convinced that it only requires a fair trial to render its use general. Purchase liq. ammonia fortis s.g. ·880, in capsuled bottles or Winchester quarts. The present price is not more than sixpence per pound. Use a measured quantity, say two ounces, in a saucer placed at the bottom of an air-tight box; lay the sheet to be fumed on netting stretched an inch or two below the lid; the distance between the liquid and the surface of the paper should be fifteen inches at least. To ascertain the

* Concluded from page 42.

proper time to fume any given sample of paper—for the different makes vary enormously—it is better to start by exposing the paper in the box for one minute; cut off a corner and expose it to daylight. If the colour be red as it darkens in the light, the action has been insufficient, and it will be quite safe to return the paper for at least another minute; at the end of this time another small piece may be cut off and exposed as before. This time it may print grey, afterwards becoming purple; this is an indication that the paper is sufficiently fumed for all ordinary purposes. The sample of paper we have been using for the last few months requires thirty minutes' fuming, and a few years ago we were using paper which required an hour and a-half. When there is much moisture in the atmosphere, and a weak silver bath is employed, a peculiar mottled appearance is sometimes seen, although the purple colour has been attained. This indicates the necessity for a longer period of floating on the silver solution, followed by a prolonged fuming until the blue stage has been reached. As a rule, paper should be floated until it is seen to lie perfectly flat on the solution, whether it requires three minutes or ten to obtain that result. When paper has been acted upon too long by the ammonia, also when not quite dry, a grey metallic lustre and generally flat appearance is obtained. Such prints will not tone well; neither will burnishing improve them very much.

On the subject of preserved sensitive paper I can say but little. Like others, I have made many experiments, ranging between citric acid of at least fifteen years ago, and carbonate of soda leaves of a later period. Although I have preserved paper perfectly white for more than a year, I cannot say the results are preferable to those obtained on paper freshly silvered every day. The formula used for preserving the paper I have just alluded to is as follows. After sensitising in the ordinary way, and while the sheet is wet, the back of the paper should be floated, for the space of five minutes, on the following solution:—

Picked gum-arabic	3 ounces.
Water	100 ,,

When dissolved, add—

Citric acid	2 ounces.
Tartaric acid	2 ,,
Strong hydrochloric acid	2 ,,

The paper should be dried, and packed in a close metallic case.

Vignetting is a troublesome operation unless one is constantly practising; and amateurs, as a rule, would rather print their pictures plain than be bothered with cutting out and adjusting masks, without any very certain knowledge as to the results they are likely to obtain. Probably the shape is suitable enough if it were looked after; but the system of placing it in position, and leaving it to the glorious uncertainty of chance, is not a system favourable to good work. Who among us has not occasionally forgotten or neglected a vignette, and upon removing the print from the pressure-frame discovered too much this side or too little that—a sort of one-sided effect.

I won't ask your permission to let me wade through the dozen and one different ways of obtaining a vignette, since a recent description of every practical method has been made familiar to us in the *News;* but will merely mention that any suitably shaped opening in an opaque substance would give all the blending that can be desired, if placed in a diffused light at sufficient distance from the negative, to produce a well-softened outline. An arrangement similar to the one I now show you answers very well for ordinary negatives.

Example 5.—In a case of very thin or under-exposed negatives the opening may be covered with tissue paper, ground glass, or a plate coated with purple dye dissolved in collodion and spirit varnish. When the picture is half printed, should there appear to be any deficiency in blending, the smaller mask may be replaced by a larger one, and for some subjects a brief exposure may be given, removing the vignetting mask entirely. Some negatives will not give such good results printed out to the extreme limit of their dimensions; and it is not desirable to vignette them, neither is it convenient to print only so much as is really good, thus reducing the size materially. Under these circumstances a mask of the required size and shape, with plenty of margin, is secured to the faulty negative. Prints from this masked negative will have white margins. In everyday practice this white margin is given a tint somewhat lighter than the general depth of the subject. This is done in the following manner:—

Example 6.—The zinc shapes now being passed round will be found to exactly fit the paper masks, any number of which may be easily cut with a sharp penknife.

Two blocks of zinc are cut to the size of every shape used, one being a little smaller than the other. A mask is cut from sensitised paper from the larger zinc block, and the counterpart or inner portion is cut from the smaller block; the difference in the size of the two blocks being sufficient to enable the smaller one, attached to a glass plate, to block the picture entirely, and thus enable the margin to be printed deep enough to produce a pleasing effect without the necessity of a white line.

Cloud effects are produced in a variety of ways, the most practical being to obtain a series of good cloud negatives, selecting the most suitable for the subject. Without wishing to dictate in any way as to which is the best method of printing-in clouds from a negative, I will tell you which I think is the easiest.

Negatives having good density in the sky portion rarely require stopping out beyond ordinary shading. When the subject will allow it, a duster, or strip of thin sheet lead suitably arranged outside the pressure-frame, will stop most of the light from passing through that portion of the negative. Some landscape and architectural subjects would be difficult to vignette in this way; nothing short of obscuring the whole of the sky by means of an opaque substance will be found to answer. The best medium I know of is black varnish. Care must be taken not to use it too thin, and allow it to spread beyond the parts to be covered.

Example 7.—Having a print, such as I now show you, it only requires to be exposed under a sky negative for a short time in diffused daylight, covering up the picture as much as can conveniently be done. The sky negative should overlap the subject a little, unless there are special reasons for not doing so.

Heavy shadows may be softened very effectually by means of dabbing an old brush slightly charged with black varnish on the negative. To facilitate working in foliage when insufficiently indicated several retouching pencils may be bound together, thus multiplying the number of strokes with considerably less labour to the operator, and better effects are obtained than by using an ordinary stump and powdered graphite. Some photographer grind the back surface of their negatives to facilitate retouching; others attach tracing paper with the same object in view. Combining portions of one negative with portions from another requires both patience and skill. It is easy enough to print the head from one negative and the shoulders from another; but it does not always look well, either a white or dark line, caused by overlapping or the reverse, being very often too evident. Vignetting does not produce any better result, and sometimes grave errors are made in the lighting. I have always succeeded better by cutting out accurately the portions required from untoned prints of the various negatives, using a sharp penknife for the purpose. If a line of any kind be perceptible when the parts are combined it is better to let it be a white line, for this can easily be removed by the finishing.

There are a great many matters connected with this subject which might occupy the attention of our Society for several evenings. It is manifestly impossible for me to deal with more than a tithe of them just now. Before closing, however, I wish to call your attention to a method of testing the quantity of silver contained in any given solution—preferably an acid solution. In this tube is placed some pure solution of nitrate of silver, and in this one silver solution *plus* nitrate of potash.

Example 8.—This mercury bulb, termed an argentometer, is so indexed that floating in distilled water at 60° F. it stands at zero. If 100 grains of silver nitrate be added to each ounce of distilled water the bulb should register 100°; if I were to add barium or ammonium nitrate instead, I should get a very different result. The solution I am now operating with contains ten grains of silver nitrate to each fluid ounce of distilled water. We shall find upon testing it with the argentometer that it does not register nine grains. If this be so in the case of a pure solution, what degree of certainty can there be when operating with an old bath containing nitrates and albumen? I have also another solution composed of ammonium thio-cyanate seventy-eight grains in seventeen ounces of distilled water; this is the equivalent proportion to react volume for volume on a ten-grain silver solution. These burettes are graduated in cubic centimetres. I will run off five cubic centimetres of silver into this beaker; to it I will add a few drops of dilute nitric acid and a colour indicator, such as ammonia ferric alum. I will now run into this mixture exactly five cubic centimetres of the re-agent, and you will see the reaction is complete the moment the colour remains. Having a stock of the re-agent made at any convenient strength, preferably normal or decinormal, the greatest accuracy is obtained in testing any given solution containing silver. Those who employ the French system of measurement will find it more convenient to use decinormal solution, viz., seventeen grammes of silver nitrate per litre of water, and 7·6 grammes of ammonium thio-cyanate per litre. The silver solution is merely used as a standard test for the re-agent. Each cubic centimetre of the re-agent is equal to ·017 grammes of silver nitrate, or ·0108 of pure metallic silver; thus, in testing, we multiply the number of c.c. employed to act on each c.c. of the silver solution by that number of times, ·017. An easy way to ascertain how many grains per fluid ounce are contained in a definite number of grammes per litre, is to multiply by 70, and divided by 160; thus the decinormal solution of seventeen grammes of silver multiplied by 70 and divided by 160 equals 7 and $\frac{7}{16}$ grains per ounce—practically, $7\frac{1}{2}$ grains per ounce.

I thank you, gentlemen, for your kind attention. I should like to have illustrated my remarks more fully, but have not been able to devote much time to the subject. On going carefully over it, I find I have not touched at all on some important matters. No doubt the gentlemen who follow me on this subject will not be so remiss.

W. M. Ashman.

ON THINGS IN GENERAL.

I can imagine I see a grim smile pass over the features of a gentleman (personally unknown and, possibly, utterly unlike the mental image I have formed) with whom I lately crossed swords, as he read a communication in the December issue of the "non-commercial" *Journal* of the Parent Society—the one I mean suggesting or recommending the institution of a "school of art-photography." And has it come to this? After the conscientous endeavours of the Editors of this Journal and of other writers to show the universality of art—which is for all time, and knows neither creed nor people—that at this time, when photography as a science is advancing with rapid strides, and thus showing, with no questionable voice, that so many of its votaries have the true artistic spirit, to find any one advancing a plea for teaching "photographic art," and accorded a prominent position in a representative journal is, to say the least of it, disheartening in the highest degree. True it is that art is not mathematics, and the accepted of yesterday may be the laughing-stock of today. Put up at Christie's dry work by a certain former President of the Royal Academy, and would it fetch as many pence as it was purchased for pounds? Yet never, I doubt, would "photographic art" come to the front. I feel positively degraded at the suggestion.

Such reflections lead me to think of the recent complaint that has been made of pictures being exhibited in the names of persons who did but turn the handle, as it were—who only uncapped the lens while others went through the labour and the toil of developing. I do think the whole of the operations of taking photographs are better performed by one man; but, if they be not, surely it cannot be denied that when a man produces a number of good things—and not merely a simple picture, which may be a fluke—whatever art feeling may be indicated in the picture, or canons of art followed and their application shown, should be held worthy of recognition, whoever may have developed the plate and flashed into existence the proof of the value of his selection or arrangement.

A somewhat similar theme is touched in a letter I lately saw in these columns relative to the Bristol exhibition, where whatever enlargement is exhibited it is required to have been done by the exhibitor himself. If this rule were universal more than one exhibitor would be deprived of his spoils. This point, however, is fairly open to discussion; but when, as I am credibly informed happened a year or two ago at Pall Mall, a medallist exhibits as his own (and not as an enlargement) a picture the original negative of which he had no hand in taking, and, as is commonly believed, also did not make the enlargement—I refrain from giving my opinion of such shameless effrontery.

To leave such subjects aside, I pass to the Glasgow *conversazione*, which seems to have been a thoroughly successful affair. I trust the harmony of the evening was not disturbed by the exhibition of the Grimeo-Kistocope. What a terrible instrument it must be if its proportions are at all in keeping with its name!

By-the-bye, the coincidence that I noticed last month is rendered still further remarkable. Not only is the light screen and the bicycle-saddle illustrated in this Journal, from Mr. Crooke's paper, identical with that used by Mr. Marshall Wane, but even the camera shade also appears identical with it. Cannot one of the two gentlemen give some explanation of these parallel thoughts? I should like to know also if the plate-varnishing convenience illustrated has been actually brought into practice by its inventor, as the somewhat guarded context suggests? or is it merely an idea, and nothing more? for, as represented in the drawing and described in the text, I should say it would be worthless.

Mr. McKean's lantern carrier, illustrated in the preceding pages, possesses just the opposite characteristics, and exhibitors will be under a debt of gratitude to him, in the first place, for devising, and, secondly, for publishing, such a useful contrivance.

I want to know is "useful" the correct word to employ? for I find a large advertisement brought before my eyes every week describing a certain process as being the "most intrinsic" of photographic processes. Now, I should like to give a nice, full-flowing, rounded adjectival expressiveness to my praise of Mr. McKean's inventions; but I don't like to call it an "intrinsic." I am afraid he would not take it kindly.

Mr. W. E. Debenham's invention has, as I predicted, aroused quite an excitement, and the old "canary medium" and orange pea-green controversy bids fair to be reopened in full intensity. Experiments are being made by everybody. I have heard no one condemn the suggestion on practical grounds—and theories are like statistics, they can prove anything—yet such is the perverseness of photographic human nature that with every inducement before them people will not get out of the rut. As to my own case I candidly confess, though I use ruby light, I use it freely, so that the smallest of small prints can, at any rate in summer, be read in any corner of the room with the greatest ease; hence there is no inducement to me to change. Further: I must say that personally I cannot accurately judge of the density of a negative nor as to whether the features are "sharp" when there is a sheet or two of paper between the negative and the light. This reason would prevent me taking up the idea of Mr. Herbert Starnes's lamp if I were not prejudiced against it on theoretical grounds. As far as I can judge it only reduces the intensity of the light to a most marked extent, so that if the reflected light were intensified by a lens photographic action would proceed apace. If this view be correct, the same effect could be produced by turning down the gas or by putting an extra sheet of paper on the window when daylight is used. I cannot help feeling that the general verdict will be, like that narrated in the veracious ballad of "St. Anthony and the Fishes," which explicitly explains how—

> "St. Anthony at church
> Was left in the lurch;
> So he went to the ditches,
> And preached to the fishes,"

and after expounding all kinds of valuable truths suited to their piscine natures and erratic modes of living, despondingly adds—

> "Much delighted were they,
> But preferred the old way."

FREE LANCE.

CAMERA LUCIDA.—PALETTA OBSCURA. A STUDY IN LIGHT AND SHADOW.*

To consider the first of our united art aims, namely, the exact imitation of Nature as she appears to us and as she appears to others, the eye is the organ to which we all appeal, and I do not know a more fickle umpire, except perhaps the ear.

I had a friend once in Auckland, New Zealand, who had weak eyes and used blue spectacles for the glaring. He never was satisfied with my colouring; the yellows always had such a green appearance. "Why won't you stick to pure chrome?" he used to ask, seriously transfixing me with two blank window panes of deep indigo.

Many people are colour-blind, yet not entirely so, and more is the pity, but just on one point, *like the sunstroke of Sir Roger Tichborne;* and the worst is they are not aware of that particular point, and feel quite put out if it is explained to them. They will think the man an ass who tries to prove them wrong, for if they are strong upon any point it is on that particular one. I have proved it dozens of times in cases of partial sunstroke and colour-blindness. I mean, just a slight wipe out of the mental slate—a blurring, or, as it were, a Dutch effect in the case of sunstroke; or a delicacy of perception awanting in the colour-blindness, a gauze veil dropped over, not nearly so apparent as the blue glasses, or the lack of distinction between red and green, for Daltonism like this ought to be palpable both to the sufferer and his suffering friends.

There is also a distortion of vision apart from nearness or longness of sight which is a very troublesome agent to fight against for the producer—a little nerve gone "agee" through partial paralysis or an accident before birth—and everything is different than to any one else; or it may be that it is spasmodic and occasional in its effects, and then woe to the picture that comes under his lash (if a critic) at a moment the twisted fit is on him.

Ten artists sit down to one landscape and make ten different pictures, and the camera drops in and makes the eleventh, like none of the ten, but wonderfully like the original, as those ten different pairs of eyes will testify, in spite of their varied distortions. Ten different critics look at a picture and find out different faults, each praising as virtues the faults of the nine others. Ten women will look upon one man and ten chances to one they will all find different uglinesses about him, with the exception of the tenth, *whom he may have chosen,* and yet they will all unite in agreeing that she wasn't worthy of him; which clearly proves, I think, that this form-distortion of vision is only partial.

Realism is the passion of the day, both in writers and painters; and this passion photography is only too well qualified to gratify. To note down a scene, or describe an emotion by the aid of its most minute outer symbolism, as faithfully and as free from complexity as possible, seems to be the greatest virtue and highest aim of the modern school.

The names which I would select as samples of this style of work will be those names which, by engravings and etchings, are best known to us, and so likely to be of most use in our search after excellent examples. Amongst the old masters I would quote Albert Durer for stern realism, combining a symbolism and spirituality so refined that it is no wonder his qualities have been so long unseen by critics such as Pilkington, who says of him—"He was a man of extreme ingenuity, without being a genius. In composition copious without taste, anxiously precise in parts, but unmindful of the whole, he has rather shown us what to avoid than what to follow." Rembrandt I would take next, as we all know about him and his powers; also because he seems to be the model chosen, but in few cases followed out correctly, by photographers who desire to produce striking effects. David Teniers I would point out next, as a type of naturalism without much straining after force or effect, no elevating force or symbolic influence.

I take those three great names as samples because their manners are distinctly separate, because their systems and tricks for reaching effect are easily penetrated, and because, while I am describing characteristic works by them, and explaining as well as I can how they may be followed out with original force by photographers, you will also call to mind those specimens of their brush-work exhibited in Edinburgh during this last summer, and so follow me more easily.

All good original work is got from copying and following those who have gone before. I could quote scores of painters since the days of Durer, Rembrandt, and Teniers, down to the present hour, who gain fame only through being Durerites, Rembrandtists, or Tenierians, with

* Continued from page 41.

a little of their own personalities thrown in, as those old masters did. Durer flung in and mixed up a part of himself (which he could not keep out) along with the training of Michael Wolgemuth. Rembrandt hashed up Zwanenburg, Lastman, Pinas, with a host of others, along with the son of his own mother, to produce the mightiest giant of the art race, which we all try to copy whenever we want to feel free from the feeding bottle. It is the fate of all great men to copy. Blake says—"The difference between a bad artist and a good is that the bad artist *seems* to copy a great deal, and the good one *does* copy a great deal."

Spending lots of time drawing after the antique and winning gold medals and South Kensington certificates; fiddling over false niceties, trying to *finish*, when there is no such thing as finish in creation, far less in art; being so careful that they lose all freedom of action, freedom of thought, and produce *nothing*. That is the rubbish they are turning out of the government schools nowadays—students who labour five years at freehand outline, ten years at antique casts, and niggle the rest of their useful years amongst nude models in life schools, while the real, active copyists are vaulting over their silly heads, and digging out niches to enshrine themselves down Time.

William Hunt, the Yankee, in his *Talks about Art*, tells us about Durer and copying in his own terse way thus:—"Albert Durer with an outline knew how to make an outline look like a firm, full figure. He began with firmness, and finished with delicacy.... But he did'nt get it in a day. Hercules may have strangled a serpent when he was a baby, but there was a time when he couldn't. 'Durer worked in his own way!' No! nor did anybody else at first. They all worked in the manner of someone else, in the way they were shown. Raphael after Perugino, Vandyke after Rubens. If Albert Durer had lived in Venice he would have been a Venetian painter. As it was he worked as the old German artists had worked."

I turn from Durer to Rembrandt, as from a nature refined and gentle to a nature rugged and strong, as from a woman to a man, whose firm hand I like to grasp even better than the tender clasp of the other.

Rembrandt, the master of painting—even more than Rubens—of etching and photography, who, when better understood, will do us all more benefit than any one of the others with one exception, which I shall name presently.

The secret of Rembrandt lies exposed if we only read him aright. It is not the mass of shadow and isolated light which stamps the power and individuality of the man. These are only his tricks of trade, repeated when he saw how well they took with the public. It is the vigour and command of the man that strikes us as we probe the breadth and extreme simplicity of accessories. He is content with a bunch of carrots when they serve his purpose. The copper gigantic stew-pan would have been enough if he could have hidden a part of the exact circle; but he wanted the woman to stand out alone. The other objects were put in to support a blankness, as a little by-play, an incident by the way; but the working woman is the aim of his setting up that large canvas. He got it all in of an afternoon—the time she was plucking the fowl—that is, the master touches; the rest might be done by any one.

To imitate Rembrandt properly get hold of the first High-street, Cowgate, or Leith basket woman that you chance to meet—a herring or orange vendor will do. Take her as she sits without arranging a single fold, adding to or removing one iota about her; take her on the street or in the close, or as she squats down inside the half-darkened doorway of her own little shop. She can neither have too little or too much about her if she struck you distinctly while you passed as being picturesque. Never mind the lighting, or think to be original. As she stands, or sits, or squats, she is the woman for your camera; out with it and secure her before she can wink or know what you are up to, and you have caught the whole secret of Rembrandt's power and realistic talent. HUME NISBET.

(To be concluded in our next.)

DISTRIBUTION OF MEDALS AND CERTIFICATES AT THE POLYTECHNIC YOUNG MEN'S CHRISTIAN INSTITUTE IN CONNECTION WITH THE CITY GUILDS.

ON Thursday evening, the 17th instant, the medals and certificates gained by students in photography at the Polytechnic Young Men's Christian Institute, at the annual examination in connection with the City Guilds, were awarded to the successful candidates,—Mr. W. Fowler, M.P., occupying the chair. The large hall was crowded with the students and visitors.

Mr. Quintin Hogg, the founder and hon. secretary of the Institute, in his report for the past year, stated that the Polytechnic headed the list above all other schools in the country at the City Guilds' examination—eighty per cent. of the candidates who presented themselves from the Polytechnic obtaining certificates, while from all other educational centres the average passes were fifty per cent.

The prizes were distributed to the successful competitors by the Right Hon. the Lord Chancellor (Earl Selborne), who, in a capital speech, expressed his pleasure at being present and the interest he took in the matter of technical education, being himself officially connected with the City Guilds. His Lordship (and also subsequent speakers) dwelt at some length on the importance to the country at large of advancing technical education in the various arts and trades, alluding to the efforts now being made in this direction in foreign countries, and said that if England was to hold her own in competing with other nations still more attention must be given to technical teaching.

Classes in photography are now held twice a week at this school, under the direction of Mr. E. Howard Farmer.

APPARATUS FOR CHANGING AND STORING PHOTOGRAPHERS' BACKGROUNDS AND OTHER MOVABLE SCENERY.

THE following is the specification of an invention communicated by WILLIAM EVANS LINDOP, of St. Thomas, Ontario, Canada:—

This invention consists of a gate or switch-like frame provided with rails at top and bottom, together with a series of stalls, each having rails at corresponding heights to those of the gate to receive a background, the gate or switch being so pivoted that it may be brought opposite to any one of these stalls, so that the background therein may be readily run on to the gate for use from any one of the stalls, and *vice versâ*.

The backgrounds have rollers at back which run on the rails of the gate and sustain the background in position, and the gate is pivoted or hinged to any suitable support at one end, or at some intermediate point, and its hinge rod made double-jointed or cranked in order to enable the gate to be shifted about for altering the position of the background.

The stile of the swinging end of the gate is provided with one or more spring catches, to engage with the posts of the stalls to hold the gate while changing the background.

A spring holds the other end of the gate at the same time, said spring being attached to the floor to receive the bottom part or crank of the hinge rod, and fastened at one end only in order that the other end may slide along the floor and be depressed by the crank, which passes into a notch in the spring, whereby the hinge rod is held in the required line with the stall.

Where space will allow of it the stalls will be extended in a straight line, and backgrounds of said construction employed; but, to provide for storing the backgrounds in less space they may be made flexible by means of narrow strips or slats properly jointed together, the stalls being curved so as to turn corners or run in circles, or nearly so, if desired.

The rollers on the backgrounds are grooved for running on the rails, but grooved rails may be employed with rollers to run in them if desired, and other modifications of the details may be made.

The gate is provided with a caster wheel on its free end to prevent it from sagging, and, by preference, the lower guide rolls on the backgrounds (when used) will be located under the lower rails of the gate, to have better effect in bending the flexible backgrounds to the rails.

The invention is applicable to other scenery as well as to the backgrounds of photographers' rooms.

Our Editorial Table.

BACTERIA.—By DR. ANTOINE MAGNIN and GEO. M. STERNBERG, U.S.A., F.R.M.S.—Second Edition, with Plates, pp. 487.
New York: W. WOOD AND CO.

IN a series of articles devoted to *Photomicrography*, an attempt is being made to show its conditional applicability to meet some of the difficulties in delineating the images of minute microscopic objects, and we are now enabled to cite the above work as an example of its utility. This second edition of *Bacteria*—a work originally from the pen of Dr. Magnin and translated by Dr. Sternberg, the author of *Photomicrographs and How to Make Them*—has been very largely supplemented by a *résumé* of the latest works and opinions of some of the most eminent experimentalists and observers in this conflicting and laborious field; also by valuable original contributions of the translator.

Under the joint authorship we have now an excellent work on the *Bacteria*, with the statement of the experiments that have led to the more or less general opinion that some of the schizophytes are the cause of, at least, a few of the devastating infectious diseases, especially among cattle and poultry, if not also in man. We have, likewise, the details of the curious fact of the virulence of the author's saliva, being that of a healthy person, and of others, when injected under the skin of healthy rabbits, both before and after pure cultures of the peculiar infective micrococcus have been procured.

Very recently we have seen it stated that Dr. Friere, of Brazil, has obtained and cultivated the micrococcus of yellow fever, *Cryptococcus Xanthogenicus*. Acting upon the courage of his experiments, and advice of a medical commission, he has already inoculated five persons, under the conviction of securing to them immunity from the virulent form of the fever.

The methods which have been found successful in obtaining purity in the cultures, without which all results would be open to doubt, are especially noted. Good photomicrographs are given in heliotype plates, and in the preface Dr. Sternberg acknowledges "the technical difficulties attending an attempt to photograph the minute organisms represented." Figures from various sources are also given of many of the *bacilli*, *bacteria*, and *micrococci*. The 487 pages may be briefly divided into the classification (Cohn's), embracing the morphology and physiology of the organisms, while the additional portions, due to the translator, are given in the technology (cultivation, staining, photographing, collecting, attenuation, &c.); germicides and antiseptics (some 60); bacteria in infectious diseases (34), and in surgical lesions. Twelve plates and sundry woodcuts adorn the work, which is completed by a most copious bibliography.

The value of the book is very largely dependent upon, and increased by, the conscientious manner in which it has been accomplished; hence, it is the more to be appreciated in a subject of such momentous question and widespread interest.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

At the technical meeting of this Society, held on Tuesday last, the 22nd instant, the chair was taken by Captain W. de W. Abney, F.R.S.

Mr. A. Cowan said that a question had been asked at a previous meeting as to the advantage which had been claimed for the addition of iodide of mercury to the developer (in this case, the soda developer) as an accelerator with gelatino-bromide plates. He produced six plates, the first four of which had been exposed for a similar length of time, and had been developed in the following manner:—No. 1 with the usual pyro. and ammonia; No. 2 with the soda developer; No. 3 with the soda developer and the mercury added after a time, as recommended; and No. 4 with the mercury added to the soda solution at the commencement of development. Plates 5 and 6 were developed like plate No. 3, but had had less exposure. He could find no gain at all from the use of the mercury. He considered that it only acted as an intensifier in the same manner as it would do after fixing. When mixed, either with pyro. alone or with soda alone, the mercuric solution produced no effect, but when mixed all together the solution became muddy at once. There was, he thought, no advantage in the use of the soda developer, and none from the addition of mercury in the developer.

Mr. W. M. Ashman had experimented in the same direction, and his opinion was in accordance with that of Mr. Cowan.

The Chairman inquired whether the intensifying action of the mercury when mixed with the developer gave a permanent negative.

Mr. Cowan thought that it gave a result neither more nor less permanent than the use of mercury and hypo. generally.

Mr. W. E. Debenham considered that the use of Schlippe's salt after that of mercury was favourable to permanency.

Mr. T. Sebastian Davis remarked that the discussion showed the benefit of the technical meetings. The experiments which had been made would, doubtless, prevent many others from wasting their time on the process.

Mr. Payne Jennings observed that it was satisfactory that both experimenters had come to the same conclusion.

Mr. Debenham said that on a previous occasion he had shown a lantern to exhibit the comparative illuminating effects of a light through four varieties of medium, namely:—No. 1 side fitted with green glass and yellow paper, No. 2 with two ruby glasses, No. 3 with ruby flashed upon orange pot glass, and No. 4 with ruby glass and yellow paper. The result had shown the greatest luminosity to come through the side with the least chemical action, namely, that one fitted with the green glass and yellow paper. He now exhibited the lantern fitted for comparing other media. The same green and yellow combination was on No. 1 side; on No. 2 were cherry fabric and tissue paper, and on No. 3 were orange glass, ground glass, and white paper. The paper had been added to the last-mentioned combination because without it the light was so powerful that a fair comparison with the other lights could not be instituted. The gas having been turned down, some drawings on the wall were illuminated by each side of the lantern in turn, and the general opinion was that decidedly less could be seen by the light through the cherry fabric than by either of the other lights. Plates were shown which had been exposed simultaneously for twelve minutes at a distance of eight inches from each side of the lantern. The plate opposite the green glass and yellow paper showed less action of light upon it than either of the others, which were about equal.

The Chairman said that, bearing on the same subject, he would show some plates prepared for experimental light-testing purposes—some with chromate and some with bichromate of lead; also, some orange paper and some paper which had been given him as canary medium. He had exposed plates at a distance of four feet from an eight-candle gas jet behind each of these mediums. Canary paper was unsafe in itself, but the addition of orange paper to it made it quite safe.

Mr. H. H. Cunningham said that the paper handed round by the Chairman as canary medium was not at all like what he had seen as that material, and was much thinner.

Mr. Debenham confirmed Mr. Cunningham's observation, and added that he had found canary medium safer, produce less effect on the sensitive plate, than a ruby light of the same luminosity to the eye.

Mr. T. Bolas said that the great point was not to use too much light.

The Chairman remarked that a plate might be developed with white light kept down in quantity.

Mr. Bolas inquired whether the Chairman considered that it would be safe as a working method to use white light.

The Chairman said it would be perfectly safe if care were taken to use only reflected light and keep the plate shaded.

Mr. Davis thought orange glass and yellow glass together formed a good combination.

The Chairman said there was nothing to compare with a glass known as "stained red;" it was of deep orange colour.

Mr. Davis observed that when development was long he turned his back to the light and shaded the plate.

Mr. J. Cadett said that he had been trying yellow paper in comparison with a ruby globe, working at a distance of four feet from the light. He found the light from the yellow paper decidedly preferable for working by, and the effect on the sensitive plate was less than with the ruby globe.

The Chairman said that yellow light might do for plates containing iodide, but with pure bromide plates it was necessary to use red.

Mr. Debenham said that anticipating that objection he had, as he stated at the meeting when he first introduced the subject, exposed to the four different coloured sides of the lantern pure bromide plates as well as those containing iodide, but could find no difference in the results.

Mr. Jennings thought the best light he had used was that obtained through ruby glass and orange paper.

Mr. Cadett said he had found with that combination that a plate had fogged in ten seconds at a distance of eighteen inches.

Mr. Bolas remarked that with some persons the sensitiveness of the eyes to rays of certain colour was different from that of other persons comparing the luminosity of light of various colours.

Mr. Cowan said that some considerable interest had been excited by Mr. Debenham's method of lighting the dark room, and quite lately by a method of using reflected light only. He had combined these methods in his dark room, and had a large sheet of the green glass with four thicknesses of yellow paper in contact with it. At a distance of four inches from this glass was a gas flame, but a tin shade was arranged so as to prevent any light from the flame from striking directly upon the glass and paper. The light from the flame fell upon a sheet of the same kind of yellow paper, which was curved so as to reflect its light through the glass and paper. He had exposed three sections of a plate at a distance of six inches from the glass for periods of five, ten, and fifteen minutes. A fourth part of the plate had been kept covered. On development no trace of an image appeared on any part of the plate, which was handed round for inspection. There was ample light for working by.

In answer to a question, Mr. W. Ackland said the injury to the eyes from working in a red light that had come under his observation was a weakness of the ciliary muscle.

Mr. W. England thought it was very evident that green-yellow light might be used with safety.

The Chairman said that green and red light combined would make a yellow which was absolutely unsafe.

A question was read from the box, and the Chairman suggested that answers should be given at the next technical meeting. The question was—Which of three courses is it best to pursue in developing a gelatine plate—1. To wet the plate before developing.—2. To mix the developer completely at first.—3. To add the constituents of the solution by degrees?

Mr. G. L. Addenbrooke said that a plate wetted first, developed more slowly, and more on the surface, than one on which the developer was poured direct. In the latter case the image showed more at the back of the plate.

The Chairman remarked that much depended upon the state of the plate at the time of development. If it were very dry from the effects of climate, it might appear as if it had only had half the proper exposure. Such a plate would register three numbers lower on the sensitometer than one which was in the ordinary state. If kept for two or three months in his laboratory (which was rather humid) before development, the plate returned to its normal state.

It was mentioned that at the next technical meeting there would be the Society's two-wick sciopticon lantern in use, and comparisons of slides of various makes and of other forms of lanterns were invited.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society held on Thursday the 19th inst., the chair was taken by Mr. A. Haddon.

Mr. W. E. Debenham showed a dipper of wood, pegged together, for use in a hypo. bath for large plates. He said that some time before he had seen a dipper in use by Mr. A. L. Henderson in which there was a slot along the upright part, with a glass stud sliding in this slot. This stud caught the top of the plate and prevented it from slipping off. The present dipper had such a slot, with the addition that, at the top, the slot or groove was continued for a short distance in a horizontal direction. This allowed the stud, which was an ordinary ivory collar stud, to remain without slipping down, whilst the plate was put in place. The bottom of the dipper was a piece of wood, about ten inches long, by one inch wide, and had two deep semicircular grooves running along it. Two plates could, if necessary, be placed on the dipper, one in each groove. This was an advantage, as although, for ordinary sizes, he preferred to have several baths in use so that each plate might have time to fix properly, it would be inconvenient to have several such large baths as that to which this dipper belonged, one taking plates up to twenty inches by sixteen.

Mr. W. M. Ashman thought it very desirable to have plenty of accommodation for thorough fixation. He kept four hypo. baths in use.

Mr. A. Cowan showed a camera, understood to be of French manufacture, with a novel means of altering the position from vertical to horizontal, or *vice versâ*. The front of the bellows was attached to a circular plate which worked in a recess in the camera front. The back was attached to the base-board by a screw which could not be quite drawn out, so that it could not be lost, and on turning this screw the back was disengaged, and might be revolved and refixed by a similar screw in the desired position. There was also great length of movement, focussing from two and three-quarters to seventeen and a-half inches.

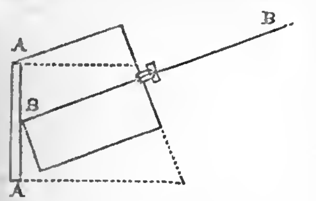
Mr. H. S. Starnes showed a variation of the lamp which he had previously exhibited, and which was contrived for portability in travelling. A base and top of semicircular shape were made of blackened tin with a vertical rim. In these rims was placed a sheet either of cardboard lined with green or brown paper, or a sheet of ordinary brown paper merely. The semicylindrical form of the card or paper gave it sufficient rigidity to support the tin top. In the base was a socket for a candle, and a rim for holding a piece of card to keep any light from passing except that which was reflected from the paper forming the inside of the lantern.

A Member inquired whether there was any difference in principle between the use of a tilted camera with a swing back and a camera with a swing front and rising arrangement.

The Chairman said that perhaps Mr. Debenham would answer the question.

The Member (continuing) said that the case was one where the lens would only cover the plate of the size wanted, so that it was not admissible to raise the front without tilting either camera or front. He thought that there was an advantage in the use of a swing front, as the lens could be raised a little and so do part of what was wanted, and that the front would not have to be swung to so great an angle to get the image central as the angle that would occur when the camera was tilted and the back swung into the vertical position.

Mr. Debenham said that there was no difference in the angle in the two cases, and put the annexed diagram on the black-board in illustration of the position. Let A A be the camera back, and B B a line from some point in the building which must come in the centre of the field. Now the lens must occupy the position in which it is drawn, whether the camera be tilted and the back swing vertically, or the front be swung and the lens raised as in the other case. It could, therefore, make no difference optically whether the filling-in of the camera took the ordinary form indicated by the continuous lines or that with the swing front indicated by the dotted lines. For his own part he preferred, as being better on principle, to use in such a case a lens with very wide angle, a rigid camera, and high rising front.



Mr. R. E. Wilkinson was elected a member of the Association.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The ordinary monthly meeting of this Society was held at the Manchester Technical Schools on Tuesday, the 10th inst.,—Mr. John Pollitt, President, in the chair.

The minutes of the previous meeting were read and confirmed. The following gentlemen were elected members of the Society, and afterwards formally introduced to the President:—Messrs. John H. Baird, Jas. H. Prestwich, and T. C. Rayner.

The Hon. Secretary then read a paper which was particularly of interest to the members of the Society, calling upon them for assistance in making the monthly meetings as interesting as possible. He (the Hon. Secretary) said he was quite aware of the difficulty to many of the members in finding original matter for papers, but thought there were plenty of subjects of sufficient interest that might be taken up by them. Say, for instance, a few practical demonstrations in the development of gelatino-bromide plates; for all knew how much more they could learn by seeing a thing done under their own eyes than by any amount of book reading. He did not advocate *every* amateur making his own plates, as the general convenience and limited consumption was not sufficient to enable them to prepare plates better, or even as good, as could be purchased from many of the more commercial firms, any more than they could prepare albumenised paper for printing. In the days of collodion dry plates things were very different; but, even then, few amateurs made their own collodion, so that it is the development of plates to which he would advise them to turn their attention for the present. There were now various methods for developing gelatino-bromide plates, with particular merits claimed for each, and a few practical demonstrations carried out in a scientific manner would, he was sure, be of interest to all. Take, for instance, the ordinary pyrogallic developer, the ferrous-oxalate, the sal-soda, the sulpho-pyrogallol, the developers in which citrates are added, the hydrokinone developers, and a new one spoken of in last week's Journal, from Mr. Newton's studio in America. Perhaps the best way to test these developers at the meeting would be to expose a number of plates of one batch, behind a negative in a printing-frame, to the light of a lamp (which could be made dark for developing). Developing trays and chemicals were, he thought, better brought by the demonstrator. After the plates had been exposed consecutively for a given time, at a measured distance from the lamp (thus ensuring the same exposure to each plate), they might each be developed by a separate developer, and the result could be judged afterwards. The developing of plates, as here suggested, could be varied in other ways, and a night might be spent in testing the rapidity of various plates by a standard developer, using one of Warnerke's sensitometers. The intensification of gelatine plates by the various methods might occupy another evening, and he (the Hon. Secretary) instanced many failures through imperfect knowledge in the use of chemicals. An evening might profitably be spent in the making of lantern transparencies, and perhaps by other methods than gelatine: for, although there has been some good work shown on gelatino-albumen plates, he did not consider gelatine transparencies compared favourably with those by many other processes he could name. In turn, the carbon process might easily be demonstrated, and he did not think the manipulation of a wet collodion plate or two would be out of place. Another subject might be *Enlarging* by the various methods, comparing argentic gelatino-bromide paper enlargements with those by other processes from the same negative. An evening could be well filled up with testing the use and value of swing-backs and swing-fronts. There was plenty to say about lenses for one or two evenings; and if they could induce some of our artist friends to contribute a paper or two for their guidance in the artistic arrangements and composition of their photographs no subject would be more acceptable or so highly appreciated. He (the Hon. Secretary) concluded by expressing his willingness to assist in whatever way his services could be made useful, assuring the members he would not shirk his share of the work when his time arrived.

The President said he hoped Mr. Chadwick's communication would be followed with practical results, and was of opinion the subjects set forth by him would prove very valuable instruction to most of the members.

The Hon. Secretary then exhibited several view lenses, and described (by use of the black-board) the diaphragms and their respective value, promising on some future occasion to read a paper on elementary photographic optics.

Mr. Lewis Morgan said he had paid great attention to Mr. Chadwick's remarks, and proposed a special vote of thanks.

Mr. E. Openshaw said he was much pleased with the information Mr. Chadwick had given about lenses and diaphragms; and although it was simple enough when explained, he was sure many of the members, like himself, were wiser after the explanation. He seconded the vote of thanks.

Mr. Rishton promised to read a paper on swing-backs at an early date.

Mr. A. Brothers said he should be glad to give a demonstration of the Daguerreotype process.

Mr. Chilton exhibited several plates showing insensitive marks round the edges. He had prepared the plates himself, and was unable to account for the cause of the markings.

Mr. Schofield said he had had similar markings on his own plates, and had, he thought, discovered the cause to be imperfect drying; in fact, he had satisfied himself that he could cause or prevent it at will.

Mr. Smith thought, with Mr. Schofield, that imperfect drying was the cause.

Mr. W. B. Wood said he also had experienced the markings, and after an alteration in his drying-box they had disappeared.

Mr. Allen Garnett had frequently developed plates with similar markings and by various commercial makers.

Mr. Edwards and several others all expressed similar opinions.

Mr. Allen Garnett showed a negative in which was clearly seen a double image on part of the plate only.

Mr. McKellen said he had had several similar.

Mr. W. B. Wood believed the cause was from the stop in the lens not being put in its proper place, and allowing light to get under the stop.

Mr. Chas. Harris observed that he had a photograph which he purchased in Malta, a short time ago, showing two ships, whereas there was only one in the actual view. He promised to bring it to the next meeting.

Mr. John Warburton presented to the library of the Society Thomson's translation of Gaston Tissandier's *History and Handbook of Photography*, and a vote of thanks was passed.

Two questions were from the question-box, respecting lenses, were replied to by the President.

The albums and folios of the Society were brought out, and it was suggested that as they were so full of pictures new ones be provided. Mr. S. D. McKellen promised to present six landscape prints as soon as the new folios were ready.

After a very interesting and pleasant evening, the meeting was adjourned till February.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

The sixth general meeting of the Association was held in the Religious Institution Rooms, on Thursday, the 10th instant,—Councillor Robertson in the chair.

The minutes of last meeting and of the *conversazione* were read and approved.

The Chairman then invited the members to inspect a number of platinotype prints lent by the Platinotype Company. These were very much admired, and several gentlemen testified to the simplicity and suitability of the process.

Mr. J. Paton said it was the simplest process he had ever tried. He had no trouble from the very first, and exhibited some excellent specimens of work in proof of his statements. He also showed some portraits, printed both on albumenised and platinotype paper for comparison, but the general feeling of the meeting was that the gloss of the albumen print imparted an advantage over the platinotype for portraits. He (Mr. Paton) said that he had twice tried to enamel platinotypes, but had not been successful. He thought the paper supplied by the company was not suitable. The prints had always a greasy appearance after enamelling.

The question was then asked whether solar enlargements could be done on platinotype paper.

Mr. T. McLellan said it would be quite possible to do it, but that a very long exposure would be required.

Mr. Philson showed some enamelled silver prints in accordance with his promise at the meeting on the 22nd November. A discussion arose as to the best method of mounting enamelled photographs. Some of the prints exhibited (Mr. Philson explained) were mounted with starch before being stripped from the glass. The others were mounted with gelatine along the edges. The surface of these, however, were slightly dulled where the gelatine touched the back.

Mr. Paton also showed some enamelled prints mounted with gelatine. These showed no mark of the mountant, owing to his having used a thick paper to back-up the print when enamelling.

Some discussion then took place concerning the permanency of enamelled photographs, and the general opinion of the meeting was that enamelling very much increased the permanency of silver prints.

The Chairman said he had noticed a camera advertised by the Scovill Manufacturing Company, in the New York *Photographic Times*, the principal feature of which was the revolving back, which enables the operator to make either an upright or oblong picture after he has the plate in the slide. This was advertised as Flamming's patent—a truly novel instrument. He said this statement was hardly correct, and exhibited one on exactly the same principle made for him fully twenty years ago, which had also the advantage of moving so as to take eight pictures on one plate without changing the position of the lenses.

Mr. Blackley said he had never heard of either Councillor Robertson's or the Scovill Company's cameras, but he had one made quite recently on the same principle which he would exhibit at the next meeting. Votes of thanks were then awarded to the Platinotype Company, to Messrs. Paton and Philson, and to the Chairman. The meeting then terminated.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

A general meeting of this Society took place on the 7th December, 1883, when the chair was taken by the President, Professor H. W. Vogel.

Herr Schapiro, of St. Petersburg, was admitted a member, and the Chairman mentioned that Herr Schapiro had kindly promised that the series of pictures taken by him and shown at the previous meeting, under the title of *The Memoirs of a Madman*, should be reproduced as a supplement to the *Mittheilungen*.

Herr Goltzsch showed a stereoscopic camera of peculiar construction intended for the use of amateurs, which he had himself made, using a pair of opera-glasses for lenses. He also exhibited some of the pictures taken with it.

The camera was examined with interest, but the general opinion seemed to be that, in order to make it really a useful article, some radical changes would require to be made in its arrangement.

Herr Suter, of Basle, who was present as a guest, showed one of his small wide-angled aplanatics.

The Chairman spoke well of this lens, and showed an architectural view he had taken with it. He, however, remarked that the term "wide-angled," as applied to this lens, was hardly correct, as its angle was rather under 90°.

Herr Suter said it would not be difficult to make a lens of such an angle. He thought the principle fault of this lens was that its focus was rather too long. The focus of the next higher number was *relatively* shorter.

Herr Haberlandt, who had tried one of Herr Suter's larger lenses, reported favourably of it.

Herr Schwier presented to the Society a copy of his *Photographen-Kalander*, for 1884.

On the motion of the Chairman, it was resolved on this occasion and for the future to have no second meeting of the Society in December, because the second meeting of that month was usually thinly attended.

In order not to clash with the Physical Society (of which many members of the Association were also members) it was resolved to meet every second Friday, so as to alternate with the meetings of the Physical Society, instead of meeting, as hitherto, on the first and third Friday of each month.

The Chairman showed some specimen results of a new process of photo-engraving, recently discovered by Herr Obernetter. The correctness of the gradation of the lights in the specimens shown was said to be remarkable. The process is stated to be based on the use of Obernetter gelatine plates, which are transferred to copper, and then serve as a basis for a peculiar process of etching. The plates so obtained are multiplied galvanoplastically. The pictures exhibited excited an extraordinary sensation.

Herr Haberlandt recommended that the pad put at the back of the albumenised paper in the printing-frame should be of cloth instead of paper, as the sensitive paper would then keep longer white and lie flatter upon the plate. He also spoke of the use of a trace of hyposulphite of soda in the development of under-exposed gelatine plates. He complained that plates so treated went back a great deal in the fixing bath, and was recommended to use that addition to the developer with great care and only to add it to the developer at the end of the development.

The Chairman again showed some of the portraits he had collected in the course of his journey through America. Amongst them the work of Rocher, of Chicago; Cramer, of St. Louis; and other well-known names were represented.

The question-box was then opened, and its contents having been disposed of, the meeting was adjourned.

Correspondence.

GELATINO-CHLORIDE FOR TRANSPARENCIES.

To the Editors.

Gentlemen,—I note in your issue of January 18th some questions put by a gentleman signing himself "Demarr," and relating to my remarks previously made in your columns on contact printing with gelatino-chloride emulsion. I think the questions about the printing are not difficult to answer, and I gladly assert that if no greater difficulties present themselves to "Demarr" than those he suggests, he will, in a very short time, completely master the process I was trying to popularise.

To retain my gelatino-chloride plate in contact with the negative to be copied, I simply put them face to face in a well-made printing-frame. A proper printing-frame—for all purposes—has a plate-glass front, a good, thick pad, and *good* springs, sufficiently strong to keep the plates in contact even if one be slightly curved, but not strong enough to break any ordinary plate. I have a great many 10 × 8 transparencies produced in this manner, and I never had a smash. I do not think "Demarr" need apprehend any great mortality among his negatives from this cause if he use or buy decent plates; still, I admit the force of his objection so far as it goes.

As to an unvarnished collodion negative: well, I should like to back myself to produce a contact positive even from that; but if I felt myself diffident, or fearful of scratching, I should probably varnish it or pour thin gum solution over it. Again I admit the force of "Demarr's" objection; for of a truth I should not make a practice of contact printing from collodion negatives before giving them at least a very thin coating of something.

Lastly: "Demarr" argues that if a photographer sell glass positives others may copy them. He has me on the hip this time, just as he would have those pirates if his negatives were copyright. I am not a lawyer, nor even a professional photographer, but I calculate silver prints can as easily be copied without infringing the law as glass positives.—I am, yours, &c.,

Craigcleugh, Langholm, N.B., January 19, 1884. Andrew Pringle.

FUMING SENSITIVE PAPER.

To the Editors.

Gentlemen,—At the commencement of your article on *Fuming Sensitised Paper*, page 34 of the present volume, you refer to my experience in the ammoniacal treatment of paper, and appear to be in doubt as to whether the experience was gained in America or this country.

Now, although I have every respect for Americans and American institutions, I think it is due to the photographers of this country for me to say that I took my first lesson in fuming paper from Mr. A. L. Henderson, of London-bridge, as far back as 1863—three years before the publication of the *Silver Sunbeam*. During my travels in America, soon afterwards, I met a great many photographers who had not the most vague idea of ammonia fuming, many of whom might, if they chose, say when and who gave them their first instructions. Before fuming became so general many photographers used a ninety-grain solution who would not care to admit it now.—I am, yours, &c., Wm. M. Ashman.

3, *Amersham-road, New Cross, January* 23, 1884.

"A TRADE QUESTION."

To the Editors.

Gentlemen,—It is a very great pity that, assuming the facts as stated by "X. Y. Z." in the Journal of last week to be correct, he did not give us the *name* of the firm who are doing their best to injure professional photographers. It is most sincerely to be hoped that if the name be made public all photographers will make it a matter of duty to have nothing whatever to do with such a firm.

I can draw my own conclusions as to the firm in question, and will take care that neither directly or indirectly will I have anything to do with them so long as they are doing their best to injure professionals.—I am, yours, &c., Z. Y. X.

January 22, 1884.

"PHOTOGRAPHIC EXHIBITIONS."

To the Editors.

Gentlemen,—I am glad to see that some of your readers are drawing attention—not before time—to the treatment of pictures at photographic exhibitions, and I beg that you will allow me a little space to enlarge on the ideas so admirably expressed in Mr. Lyddell Sawyer's letter of last week.

I, too, was an exhibitor at the Newcastle Exhibition and I can truthfully say that I spent many months in preparing negatives for it. I appeal to you whether, after a man has studied art in all shapes and forms, burning the midnight oil and rising with the lark; after endeavouring to breathe art into inanimate photography; after educing from the inmost recesses of his soul noble aspirations and delicate subtleties which might elevate photography to a higher and a prouder position than it has ever yet occupied;—I ask you, gentlemen, whether it is right that these splendid results should be liable, at the whim of any member of a hanging committee, to be wantonly wasted in the dim obscurity of some dark corner? and whether the continuity of an epic series should be broken by pictures being distributed over all the nooks and corners of an exhibition room?

This is what happened to me. I may say, with all modesty, that I have done my best to get a thorough knowledge of art; and I think, with Mr. Sawyer, that our talents, such as they are, should not meet with a return like this. I, like Mr. Sawyer, drew the attention of the Hanging Committee to my pictures; but, as I had not the honour of previously exhibiting them at Pall Mall, I suppose I did not get even the attention which Mr. Sawyer got, for mine were hung in odd corners, on the floor, and in the worst lights. Mr. Sawyer says he got four of his hung together, but *no two* of mine were.

It is, as Mr. Sawyer cleverly puts it, highly improper that a committee, appointed simply because they have leisure, and quite without reference to their powers of discrimination, should be able to shatter the chances of competitors.

I think that though Mr. Sawyer, with a politeness which does him credit, says he will refrain from commenting on the discourtesy shown him, it is a matter which should be brought before photographers; and I, for one, am not prepared to keep my opinion to myself.—I am, yours, &c.,
January 21, 1884. E. G. O.

To the EDITORS.

GENTLEMEN,—There was a somewhat noticeable letter in the Journal last week on the above subject. An exhibitor at Newcastle-on-Tyne complains that his pictures were not hung as he wished, although he took the trouble of telling the Hanging Committee exactly what he wanted. This does seem too bad.

It is generally understood that hanging for an exhibition of any kind is an invidious, a laborious, a difficult, and an utterly thankless task; but if each exhibitor would kindly attend with his pictures and explain exactly how and where he wished to have them placed, the work of the hangers would evidently be much lightened. As there could not possibly be any difficulty in fulfilling the wishes of all the exhibitors, and in giving to each one of them the best light and the best position, the exhibition would *probably* be a great success.

To turn this probability into a certainty it would only be necessary to provide a medal for each exhibitor, or, preferably, for each exhibit.—I am, yours, &c., K. ALNWYKE BROWNE.
January 22, 1884.

Notes and Queries.

J. C. BROWNE, D.D., asks:—"Is it possible to get the platinotype tone with the ordinary albumenised paper? Will chloride of platinum do it? If so, could you give me the formula?"

I AM about building a new studio. Being naturally desirous of constructing it on the most approved principles, I ask your kind help and information.—W. J. BYRNE, Richmond, Surrey.

KINDLY let me know if it be necessary, in the matter of copyright photographs, to brand them as such in the case of their being published, or if they can be sent out simply with the name of the subject on them.—C. A. M.——In reply: Such "branding" is unnecessary.

IS a gentleman whose portrait has been placed in a showcase as a specimen legally entitled to smash the glass and destroy the portrait, merely because we omitted to remove it immediately or soon after receiving a request from him to do so? The opinion of brother photographers will be esteemed.—BROKEN FRAME.

I AM about to build a studio. Can you kindly give me any information on the subject? or if there be a book published on the construction of studios say where it may be had, and you will greatly oblige,—JOSHUA MADEN.——In reply: There are several valuable articles on this subject scattered through back volumes of this Journal, but there is no book devoted to it.

H. HOLDEN says:—"Would you kindly let me know, through the medium of your valuable Journal, what lens you consider best—whether landscape or portrait—and whose make would be best suited to all kinds of direct enlarging from the *carte-de-visite* negative, from $6\frac{1}{2} \times 4\frac{1}{4}$ up to 24×20?"——In reply: Any good *carte* lens will answer the desired purpose. Let the lens be made of moderately long focus, and when employing it for this purpose let the back lens be placed next the negative.

Now that gelatino-chloride seems to be coming to the front, would you allow me to suggest that some enterprising firm should supply gelatino-chloride paper? If I remember rightly, Captain Abney demonstrated the beauty of this process in his lectures before the Society of Arts two years back. I have several times since tried to get paper prepared in this way, but have failed. I am sure there would be a demand for the paper—perhaps greater even than for the gelatino-bromide paper—owing to the variety of tones obtainable.—H. G. M. CONYBEARE.

J. INGHAM inquires:—1. Would a plain bromide emulsion act as well as chloride or bromo-iodide for coating canvas for enlargements?—2. What is a *good* intensifier that also acts as a brightener of negatives?—3. For general purposes, for an amateur, what kind of lens may be recommended?—4. Who was the inventor of the gelatine dry plates? and who first sold them or advertised them in the Journal?—5. A good runner runs (say) one hundred yards in ten seconds; that is, one inch in $\frac{1}{360}$ secs., and a quarter of an inch in $\frac{1}{1440}$ secs. My shutter only works to $\frac{1}{250}$ secs.; how far ought I to stand from the runner to take a sharp picture?

LENS asks:—"Will any reader inform me what is the shortest distance required by law to enable me to build a wooden shed near any other building?"——To a second question put by this correspondent we reply: Any oil lamp will do to retouch by, if you use a fine piece of ground glass behind the negative, or reflect the light on to a piece of white paper.

G. B. R. says:—"I am greatly pleased at the idea of your starting a *Notes and Queries* department, because (if you will pardon my saying so) your 'Answers to Correspondents' column is of no use whatever except to individual querists, owing to the suppression of the question. The answer, 'Yes, certainly,' may be all important to the 'A. B.' or 'X. Y. Z.' to whom it is addressed, and who, perhaps, may have put a question which is amply answered by it; but how much is the general reader benefited thereby? My idea of a proper 'answer' is one that affords the reader an idea of the question that has been asked."

F. P. wants help. He uses 165 ounces of silver nitrate for sensitising paper. The cuttings—that is, paper ash—give him twenty-five ounces of silver; the residues only eight ounces. What is wrong with his mode of treatment of the latter? The first two washing waters are saved, and thrown down with common salt about two handfuls a day, and the clear water drawn off about twice a week. The prints are given a third washing in acetic acid and water, which is thrown away. No attempt is made to save hypo.——In reply: "F. P." has quite overlooked a fertile source of recovering silver, viz., precipitating the precious metal from the hyposulphite fixing bath by the addition of sulphide of potassium. After trying this let him report again.

IN reply to the query of "A. B.," who inquires the best way to utilise sensitive plates that have been accidentally exposed to light, I would advise that the films so exposed be scraped off the glass and thrown among the waste to await recovery of the silver.—C. D.

GENTLEMEN,—I beg to tell "A. B.," who appears to have had his plate-boxes opened by the custom-house officers, that neither by chlorine water nor by acid nitrate of silver solution of any strength will he be able to get them restored to their primitive state. This information is of a decidedly negative character, you will probably say. Well, some day—perhaps soon—I may ventilate my ideas with reference to this, and describe some experiments I have now in hand.—BOZ.

I note the query of Geo. S. King (whom I recognise as a fellow collegian) with respect to the publication of Newton's method of preparing extra sensitive collodion emulsion. When I was in New York, in the autumn of 1882, I made special inquiries concerning this process, the results of which I had seen; but upon being referred to a publication of the same in a local journal, I found it so vague and so full of generalisms as to lead me to conclude that the author of the article wrote it, to some slight extent, in the interests of secrecy?—that is to say, he did not seem to "make a clean breast of it," although, from the very construction of his sentences, I felt morally certain that he knew all about it. These observations of mine will possibly fall under the eye of the writer in question, and I hope they will have the effect of "drawing him out;" for a sensitive collodion emulsion is a thing devoutly to be wished for.—THOS. HOLLAND SEDLEY.

If "Teacher" will make use of a citrate in his dark room, he will have no great trouble in developing over-exposed plates. I should recommend him to keep by him always a solution of citric acid, and one of citrate of soda—say ten per cent. in strength. When he begins to develope he should use the full quantity of pyro., with only half the amount of ammonia and bromide he would use for a properly-exposed plate. The image will then come up much less quickly, and enable him the more speedily to counteract over-exposure, and yet not lose any great amount of time. If the image come up with such rapidity as to show a very considerable over-exposure, let him raise the plate from the developing solution as soon as possible, and instantly flow over it some of the acid solution. This checks all development, and after the plate is washed for a short time it can be proceeded with almost as though it were an undeveloped plate known to be greatly over-exposed. The addition of a solution of citrate of soda in such quantity that about four or five grains is given to each drop of ammonia will then cause the action of the developer to be so modified that seven or eight times the ordinary exposure would have to be given before it would bring out a proper image. Citrate of ammonia has still greater retarding action, a few grains to each drop of ammonia allowing twenty or thirty times a correct exposure to be given without spoiling the negative.—G. WATMOUGH WEBSTER.

Exchange Column.

I will exchange an oxygen generator and gas holder, Marion's strong cameo press, and cabinet rolling machine, for movable comic lantern slides and chromotropes.—Address, 2, Hall-street, Colne, Lancashire.

We will exchange a 12×10 Kinnear camera, with two single and three double backs, for a 10×8 Dallmeyer's rapid rectilinear, thirteen-inch focus.—Address, YORK AND SON, 87, Lancaster-road, Notting-hill, W.

We will exchange lantern slides, by Joseph, Scarboro', and moving comic ditto. Wanted, symmetrical or rectilinear lens, copying camera, interior backgrounds, accessories, &c.—Address, SMALLEY BROTHERS, Fleetwood.

I will exchange a twelve-inch square studio camera, swing- and repeating back, screw focussing, studio camera stand, Emmerson's head-rest, cabinet rolling-press, two show-cases, and a variety of other articles. Wanted, portrait and view lenses by good makers.—Address, G., 157, Victoria-road, Aldershot.

I will exchange a Waterlow's automatic litho. press, sixteen-inch bed, stones, and ink slab, for condenser or photo. lens.—Address, D. 10, Spencer-road, Holloway, N.

I will exchange a two and a-half-inch portrait lens, in good condition, for full-plate lens or a camera, 8½ × 6½, in good condition; difference adjusted.—Address, J. Warwick, Sheffield-street, Carlisle.

Wanted, ferrotype material, folding tripod, or what offers in exchange for a large lamp, 30 × 25, for taking portraits by magnesium light, and a small quantity of magnesium ribbon?—Address, Photographer, 53, Clifton-street, Exeter.

Wanted, to exchange, patent "Eclipse" light apparatus for taking portraits by night or in dull weather; also, mahogany enlarging camera for portrait or group lenses or magic lantern, or offers.—Address, Beta, 61, Chapeltown-road, Leeds.

Wanted, a cabinet burnisher or camera, half- or whole-plate sliding-body, in exchange for French accordion by Bussoon, 10 keys, with row of semi-tones and three basses, in good order.—Address, N. S. Brown, 38, Balfour-street, Leith-walk, Edinburgh.

What offers in exchange for set of books (list sent on application) on Chemistry and Physical Science, landscape camera, 12 × 10, two slides, Marion. Wanted lens, Ross or Dallmeyer wide angle, 24 × 18.—Address, Alfred Cox, 30, Park-row, Nottingham.

I will exchange a good rolling-press, with glass bed and seven-inch roller, also a large dark slide for plates up to 26 × 26, for lantern transparencies, landscape quarter-plate camera (bellows-body), or anything useful in lanterns or photography.—Address, J. K. Townsend, Woodbine Villas, Carrington, Nottingham.

I will exchange three superior gem lenses, quarter-plate camera, lens, and tripod, powerful steel cabinet embossing-press, without dies, and The British Journal of Photography for the years 1882-83 complete, and half-a-year of 1881. Wanted, background, studio accessories, or open to offers.—Address, F. Rubbra, Stony Stratford, Bucks.

I will exchange a Seavey's background, interior, a large number of lantern slides, a Dallmeyer's 12 × 10 wide-angle view lens, six chromotype printing frames, for anything useful for the studio; furniture preferred. Also two backgrounds, interior and exterior, two chromotype, *carte*, and two cabinet printing and tinting frames, to print three at a time, for anything useful for the studio.—Address, Graham Glen, 1, Cary-parade, Torquay.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

Photograph Registered—

Charles Johnson, photographer, 43, Nethergate, Dundee.—*Photograph of the Tay Whale Suspended from Crane in Dundee Docks, January 12th, 1884.*

Walter Reeves.—See answer to J. Berryman. Your failure appears to be due to the same cause.

B. Bentley.—A quarter-plate portrait combination will answer quite as well as a lantern objective.

Pyro.—The same formula as for the ferrous-oxalate solution used for developing will be the best for the purpose.

H. G. Baliol.—The manufacturers do not supply the masks retail. You will have to procure them through some of the dealers.

Mask.—That portion of the subject will be dealt with next week. You will have to wait till then for the necessary information.

V. (Dublin).—In reply to your query: we believe artists emigrating to the colonies would find themselves in no better position than in this country.

Lantern.—An ordinary magic lantern, fitted with a portrait lens, will answer the purpose; or you can employ an ordinary camera and lens if you choose.

J. F. C. (Troy, N. Y.).—There has been no English translation. Apply direct to Dr. Liesegang, Dusseldorf. We are unaware of the publishing price of the work.

James Ring (Greymouth, N. Z.).—Your letter received. As you have not given us the address of your brother (W. S. Ring) we are unable to communicate with him.

S. E.—Perhaps your developer is not acid enough, or you do not use sufficient bromide in it. See to these matters, and if you find no improvement write again.

W. S. Watson.—You will be able to procure aurine from Messrs. Hopkin and Williams, Cross-street, Hatton Garden. They will also supply the other materials you require.

J. H. N.—Copy of advertisement received, but you omitted to enclose your address where replies are to be forwarded. Send address and some stamps for postage of replies.

A. Beddoe.—So far as we are aware the plates are not sold in this country, and you will, therefore, have to procure them direct from Paris. We do not know the address of the manufacturers.

Experimentalist.—Nothing more has been published on the process than was contained in Major Waterhouse's paper. Some amount of experience is, of course, necessary to work this, as every other process, successfully.

Novice.—The reason of the want of detail in the shadows is that the shutter works too rapidly for the plates. The remedy is either to adjust the shutter so that it shall act more slowly, or to procure more sensitive plates.

Bradshaw and Son.—The machine named is not an article of commerce. You can procure the specification at the Patent Office, and make one for yourselves as the patent has expired. No similar apparatus is in the market.

S. A. J.—Whatman's drawing-paper may be procured from any artists' colourman. The manufacturers will not supply so small a quantity as two or three quires; possibly they might supply you with a ream or two, but we cannot say positively.

Homo.—The best plan of drying gelatine negatives quickly, without fear of their running, is to immerse them in strong methylated spirit for a few minutes. If two changes of spirit be used they will dry very quickly, indeed, if put into a warm place.

Hertfordshire.—The company formed to work the process has ceased to exist for many years. The pictures, for which greater permanency was claimed, proved to be as fugitive as those produced in the ordinary way. The process is now never worked.

A. Woodford.—The specimen transparency is much too dense for enlarging from. It is not to be wondered at that you can only get hard and crude enlarged negatives from it. It is also under-exposed. Try again with a new transparency that is more fully exposed and much thinner.

C. A. Cartwright.—There are several reasons why collodion negatives sometimes split off the glass as they dry. Dirty glass is a very fertile source of this trouble. A too acid bath has a similar effect. If the collodion be of too heavy a character it will frequently split from the glass as the negative dries.

Albumen.—As the stains do not rub off with the cotton wool it is clear that you continued the development too long after they made their appearance. In future, so soon as any staining is apparent, put the plate under the tap and rub it off, well rinse, and recommence the development; with a fresh solution all will go well.

J. Berryman.—The fault appears to be that you have used too much heat in the muffle, or you have kept the picture in too long. Try less heat, and a shorter duration. If this do not overcome the difficulty write again, and give us full particulars of your method of working. We presume the picture was sufficiently toned in the first instance.

M. A.—Good pictures can certainly be taken in a studio such as shown in your sketches. On the whole, we should prefer to have the sloping glass roof continued, a foot or so lower—say to three feet—six or four feet from the floor. This will make the skylight steeper, which will prove an advantage. Your plan shows four feet. It will also be better to have only five feet six inches, or six feet, opaque at each end, instead of seven feet and nine feet, as you propose.

Received.—A. F. Genlain. In our next.

Photographic Club.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 30th inst., the subject for discussion will be on *The Preparation of Lantern Slides.* This being an evening devoted to the exhibition of slides in the lantern, members and visitors are invited to bring interesting subjects to be shown.

Employés' Dinner.—On the 17th instant, by the kind consideration of Mr. Norman May, photographer, Malvern, his *employés*, with a few of their friends, were enabled to spend together a few very pleasant hours of social recreation. The party numbered in all about twenty-five. They assembled in the new, handsome, and spacious rooms of the Beauchamp Hotel, where a bountiful and elegantly-served repast was provided. The time that remained after dinner was filled up with mutual congratulations, song, and merry chat—all enjoying themselves heartily.—*Malvern Advertiser.*

METEOROLOGICAL REPORT.

No. 1239. Vol. XXXI.—FEBRUARY 1, 1884.

GELATINE PELLICLE.

At this period of the year it is the practice of many photographers, both amateur and professional, to devote a portion of the time which the dull season leaves on their hands to the preparation of a stock of plates to be used when brighter weather arrives. Others, again, content themselves by preparing a stock of emulsion to be bottled off and preserved by means of alcohol or other convenient antiseptic; while still a few others prefer to dry the emulsion and store it in the form of "pellicle." But, though the latter form is in all respects the more convenient in which to store the sensitive material, the trouble involved in its preparation is sufficient to deter a very large number from utilising its advantages.

The chief trouble lies in the difficulty of drying the "pellicle," or emulsion, after it has been freed from soluble matter by washing. It is true that a certain amount of heat may be employed to hasten the operation; but the danger of causing decomposition of the gelatine limits this power within certain bounds, and, at the best, the operation is a tedious and troublesome one. Alcohol, too, may be employed to displace a great portion of the water contained in the solidified emulsion; but here, again, an objection is raised by many on the score that alcohol exercises an unfavourable action upon the sensitiveness and other qualities of the emulsion. Certain it is that alcohol does modify in some respects the character of an emulsion; but we are not prepared to say that such action is an injurious one.

As the question presents itself, then, the difficulty in pellicle-making rests in getting rid of a certain quantity of water in as effectual and rapid a manner as possible without setting up decomposition of the gelatine. The first and most natural step towards improving matters that will offer itself is to reduce the quantity of water originally employed—in other words, to make a more concentrated emulsion. But, unfortunately, this is seldom possible; for, in the majority of processes of emulsification, the quantity of water employed forms an element of equal importance with the quantity of any of the other ingredients, while in many instances it is difficult to keep the bulk of emulsion within necessary bounds in consequence of the proneness of the gelatine to absorb water during washing.

But by adopting the principle of Mr. W. K. Burton's precipitation process we get rid of this difficulty entirely, and it becomes possible to make an emulsion of almost any degree of concentration without the slightest interference with its sensitiveness or its physical qualities. The preliminary stages of emulsification are performed in any of the ordinary ways, sensitiveness being gained either by prolonged boiling or by the addition of ammonia, and the silver bromide is subsequently allowed to subside. The precipitate is then washed in two or three changes of distilled water, and allowed to subside completely after each change. The quantity of gelatine to be added is soaked well in water, and, when, swelled, added to the precipitated bromide with no more water than it has already absorbed, and, when liquified by heat, thoroughly incorporated with the sensitive bromide. This thick emulsion, when spread out in thin layers, dries with considerable rapidity, and presents no special features of difficulty to deter any one from making pellicle.

We may append the particulars of a batch of pellicle made in this manner:—One ounce of silver nitrate, thirty grains of gelatine, and three minims of nitric acid were dissolved in ten ounces of water. 300 grains of ammonium bromide were then dissolved in another quantity of ten ounces of water, and the two solutions carefully mixed at a temperature approaching boiling point. The mixture was boiled for one hour, allowed to cool, and then rendered very slightly alkaline and set aside for the bromide to settle. This occupied three or four days, in consequence of the large excess of soluble bromide. Once settled, however, the precipitate on subsequent washing subsided more rapidly, the operation being repeated three times, and, finally, the bromide was closely drained. One ounce of gelatine, having been previously swelled in water, was now added, and the beaker immersed in hot water, the contents being energetically stirred during liquefaction. This being complete the bulk was found to be about four ounces. This quantity was poured on to a 12×10 glass plate previously polished with talc, and formed into a dish by pasting strips of paper round the edges. When set the plate was placed in the drying-box and dried in the usual way, which operation occupied, without special heat, between two and three days. If cut into strips the emulsion may be peeled from the glass while still moist, and hung upon strings in the drying cupboard, when its desiccation takes place much more rapidly. Or it may be spread upon collodionised glass and stripped in a single sheet either before or after drying. Upon re-solution, the collodion film will, of course, remain undissolved and be removed by filtration.

COMBINATION PRINTING.

In our former articles on this subject we have dealt with the methods usually followed, both in silver and carbon printing, when the combination is made in the print itself. Now, as double printing with each impression is of necessity a troublesome operation, it is, therefore, more convenient, when large numbers are required, to combine two or more pictures into one negative, so that the prints may be obtained at a single operation. The usual plan of accomplishing this is, first, to make a combination transparency, and from that to produce the negative, either by camera or contact printing.

In our volume for 1882 (see pages 15 and 27) we described a means of making combination transparencies, containing the best portraits from two group negatives which had been taken in duplicate on purpose to ensure the best results attainable. In those articles will be found practical details which are applicable to the production of combination transparencies generally, and to these the reader is referred for further information.

At one of the recent meetings of the Photographic Club—when the subject of combination printing was under discussion—Mr. B. J. Edwards explained a plan he had once successfully employed to make a combination negative. It may be well, in the first instance, to explain what had to be accomplished. One figure, out of a group of several taken out of doors, was required on a larger scale for publication as a separate portrait, and it was also desired that it should appear as if taken in the studio. As a very large number of copies had to be issued, double-printing each impression was quite out of the question.

It was managed in the following manner:—In the first place, all the figures in the original negative, with the exception of the one required, were stopped out, as was also the background. Then a transparency of the figure—of course with a white background—was made on a sheet of talc. Next, some accessories with a background were arranged in the studio, and a negative taken of them on a scale suited to the figure. When finished, the space in this second negative where the figure had to be introduced was stopped out—the transparency, already made, serving as a guide for doing this. From this negative a transparency was also made on talc. Then the two transparencies were adjusted in position, one on the other, and secured together. Next, from this compound transparency a negative was made in the enlarging camera. The plan employed by Mr. Edwards on this occasion answers very well, as the thickness of talc intervening between the two images does not perceptibly interfere with the sharpness in the reproduction. But, unfortunately, as Mr. Edwards explained, this plan is only applicable when the original is of small dimensions, as there is a difficulty in obtaining perfect sheets of talc larger than four or five inches square.

This difficulty may, however, be overcome, if we take the transparencies on glass plates—previously waxed, or treated with French chalk—and then transfer the film of one or both of them to a thin sheet of gelatine or other transparent medium. Or the figure transparency may be allowed to remain on the glass, provided that of the background be on a very thin plate, and a lens of long focus—well stopped down—employed in making the reproduced negative. The trifling distance between the two images will not materially interfere with the sharpness of the reproduction; but, even if it did, the background being slightly out of focus would be advantageous rather than otherwise.

As the plan of making transparencies and then transferring the films may be utilised in so many ways in the production of combination negatives, it will here be desirable to describe how the films may be transferred. There are two methods of accomplishing this with gelatine, both of which entail but little trouble. One is that originally described many years ago in these pages by Mr. Wenderoth, namely, to immerse a sheet of thin gelatine—such as is employed for *bon-bons*—in a mixture of alcohol and water until it is softened, and then to squeegee it down upon the negative or transparency film. When it is dry it is stripped off, bringing the picture with it. The other plan is to place the transparency on a levelling-stand, and to pour upon it a warm solution of gelatine, which should contain a very small proportion of glycerine in order to avoid brittleness when the film is desiccated. When the gelatine has set it is put into a warm situation to dry. When dry the film is removed as in the former case. If sheet gelatine be used it had better be procured from some of the dealers in lithographic materials, as they supply a kind which is superior to that employed for confectionery, which, it frequently happens, is covered with the well-known "pits." Whichever plan be adopted, the edges of the plates and the gelatine should be bound together with gum paper to prevent any part of the film leaving the plate before all is perfectly dry; otherwise it will become cockled, and thereby render the transparency useless for our present purpose.

Here is another plan by which the films bearing the image may be transferred, and which possesses certain advantages over the gelatine methods:—After the transparency (or negative, for that matter) is dry, it is placed on a levelling-stand and a solution of india-rubber in benzole, about the consistency of castor oil, is poured upon it. This is allowed to dry. Then the plate is again put upon the levelling-stand and some (a good quantity) enamelling collodion is poured on, which is also allowed to dry. When perfectly dry, and not before, a penknife is run round the edges and the film removed. This compound film of collodion and india-rubber possesses several advantages over gelatine—amongst which it may be mentioned that a much thinner film may be employed, as it is very strong, yet flexible, and, unlike gelatine, is not affected by hygroscopic conditions. The pellicle transparency may even be slightly moistened, if necessary, to cement it to the other picture; whereas gelatine, if allowed to become moist, even by absorption, may so expand as to give rise to difficulty. It is almost needless to mention that when a film has to be transferred the glass should always be treated with wax or powdered talc.

Film transparencies may be employed for combining a number of negatives as a panorama, as we described in our volume for 1880 (see page 422). In this case, the transparencies are made from the small negatives, and then stripped by either of the plans described. Now a plate of glass, large enough for the combined negative, is taken and on it one of the transparencies is secured, at the top and bottom edges, with gum paper. Then the next one is adjusted in position and secured in the same manner, and so on with the remainder. Each of the small negatives, it may be mentioned, should contain a small portion of the subject of the next, and when it does it will be seen that when these portions are exactly superimposed extreme accuracy must be assured. When the transparencies are secured in position on the glass, all that remains is to cut, with a sharp penknife, through the two films in some place where they overlap, and remove the loose pieces. By this means accurately-fitting "butt" joins are secured. In cutting the films it is advisable not to make the cut in a formal straight line, but to take it through some of the deepest shadows of the picture when possible, as then the junction is the more completely hidden. From this combined transparency a negative can be made either by contact printing on a dry plate or in the camera.

Next week we shall bring this series of articles to a conclusion.

SOLIDIFYING GELATINE IN A WARM TEMPERATURE.

A TRIVIAL incident which occurred at Mr. T. Bolas's lecture at the Society of Arts, on Monday evening, involves in it a great principle. When a transparency on glass had been printed by the Woodbury process, it was found that the gelatinous ink would not set to such an extent as to permit of its being placed in the lantern for projection on the screen, in order that a certain effect might be thus illustrated. This was owing to the warmth of the hall in which the lecture was delivered.

Without staying to inquire into the degree of temperature which proves detrimental to the effective manipulation of this ingenious and admirable process, we believe, from experiments made in a different, although somewhat analogous, direction, that if once this source of annoyance is recognised as something which might possibly intrude itself, the means of effectually overcoming it may always be at hand and in readiness to be brought into requisition at a moment's notice.

Passing once the fact that the real preventive for such an occurrence is to employ a gelatinous ink that sets readily at a somewhat high temperature, the question for practical consideration at present is—By what means can an intense degree of cold be most effectively employed so as to cause a gelatine film to set quickly in order to bring it under the operation of drying agents? It is on record in a previous volume of this Journal that one of the causes by which the Woodbury process was prevented from achieving its deserved success in America was the impossibility of getting the ink to set during a season in which the thermometer stood between 95° and 100° Fahr.

We imagine that there are few who have much to do with the working of gelatine films, either as a fundamental element in the Woodbury and carbon processes or many others connected with engraving, collotypy, or even emulsion processes, who are not aware that when once a film is set the water may easily be driven out by means of alcohol, after which all danger of the film becoming again dissolved by heat ceases. But what is required during a season of warm weather or in a high temperature is a means of getting the gelatine solidified to such an extent as to preserve its moulded or pellicular form in contradistinction to its fluid state. Cold is, perhaps, not the only means of effecting this congealation; but in the present state of our knowledge it is believed to be so, and, fortunately, it is not difficult to subject fluid gelatine to its action. In regions where ice is easily procurable it is only requisite that a space of any required dimensions capable of containing the plate, the paper, or even the printing-press that has to be cooled, be brought to a sufficiently low temperature by having a tray of ice kept standing inside. This, however, cannot, in the very nature of things, cool the surrounding air below freezing point; but by the addition of half as much common salt as there is crushed ice an extreme degree of cold is produced. But it is not necessary to have recourse to this unless in exceptional cases.

We have cooled and dried a gelatine cast upon glass with great rapidity and in a very perfect manner by means of the following treatment:—Premising that the temperature of the room in which we operated was about 90° Fahr., and that no ice was procurable, we placed the coated gelatine plate in a 5 × 4 inch zinc tray, which, in turn, was set inside of a much larger and deeper porcelain tray, on the bottom of which had been placed a liberal sprinkling of ammonium nitrate, crushed by being roughly pounded in an iron mortar. A little water was then poured into the porcelain tray, care being taken that it should not stand more than three-fourths of the height of the inner zinc tray. It was immediately covered up by a thickly-felted, non-conducting cover, similar in character to the "cosy" employed by prudent housewives to cover up the teapot during the infusion of the fragrant "souchong," although of dissimilar form, and employed for a purpose quite antithetical to the other. After standing for a few minutes, the intense cold produced by the solution was found to have caused the gelatine to set much more firmly than had even been hoped for. A little alcohol was now poured in, to a depth sufficient to cover the gelatine surface of the glass. This alcohol contained a small proportion of chrome alum in solution. After allowing a few minutes for the alcohol to displace the water which remained in the gelatine, the plate was removed from the vessel and quickly became dry.

The means here described may not be the best in a mechanical sense that are suitable for effecting the rapid drying of a gelatine film in a very warm atmosphere; but the principle is unexceptionable, namely, congealing the gelatine by means of cold artificially produced, and then abstracting the water by the agency of alcohol.

PHOTOMICROGRAPHY.

Stereo-Photomicrography.—Early in the practice of this branch of photography it was proposed by Professor Wheatstone (*Trans. Microscopical Society*), 1852, that the microscope should be capable of rotation for about 15° round an imaginary axis prolonged through the object, the motion in reference to the stand being made in any direction; or that the object be made to rotate from 7° to 15° round an imaginary axis within itself, while the illumination remained equal, to avoid interfering shadows and pseudoscopic results. Mr. Wenham, in 1855 (see *Trans. Microscopical Society*, January, 1855, page 56), made the necessary difference in the images by stopping off alternately, on opposite sides, one-half of the effective aperture of the objective, and in those with large angular apertures about one-third of the aperture, by using a sliding stop with sharp edges behind the back lens. With high power objectives, as $\frac{1}{12}$, he found that, after obtaining a picture in one position, a slight alteration of the object, and the illumination, sufficed to furnish the necessary difference in the other picture to give stereoscopic effects when combined. It was on this plan that Dr. Maddox obtained his stereo. pictures at 3,000 diameters.

For opaque objects low powers are the most suitable, and may be used with the proper Lieberkuhn reflector, which sometimes may have nearly half of its reflecting surface stopped off by a screen of black paper for the first picture, and then rotated for the second picture; or light may be thrown across the object by a side reflector, a small condenser, or an achromatised prism. Depressions appear to be best illuminated by the Lieberkuhn. If the shadows appear too heavy the object may be slightly lighted in the opposite direction by light reflected from a white card or mirror. It is always well to screen the objective from extraneous light.

Professor Riddell, of New Orleans, suggested the use of a small equilateral prism behind the objective, which, by being slightly inclined as regards the axis of the microscope, is made to furnish one picture. The position is then to be altered and the object moved so as to bring the same part again under the objective, thus giving it a slightly varied appearance, the required inclination of the prism being from 4° to 7°, the combination of the images furnishing a stereo. picture.

Professor Rood adopted the plan of depressing the slide on either side alternately to procure the angular displacement. (See *Trans. Microscopical Society*, 1862, page 268.)

Mr. Heisch, in 1862, by an ingenious plan, adapted the half stop to the back of the objective, so that he could shut off the alternate halves, as required, by the use of a lever moved from the outside. It could take the place of an adapter to any ordinary microscope. In use, the stop is moved in the tube nearer or farther from the back lens, until the image "is equally illuminated in whatsoever position the stop may be turned." (See this Journal, October 15, 1862.)

Dr. Moitessier describes the method of making the cap to fit over the front of the objective, and points out the necessity of having the position of the stop, relatively to the image on the screen, carefully observed, so that the edge of the stop shall coincide with the vertical axis of the images. He also remarks that this method can be used effectually when the apparatus is arranged for an ordinary small photographic lens behind the prism when photographing rather large objects. He prefers to place the half stop either close before or behind the front lens of the objective, as furnishing better results. Sometimes it is advantageous to use subdued solar light from a ground glass placed near the solar focus of a long-focus achromatic condenser, when taking transparent objects. For these Dr. Moitessier also advises some form of additional stage of sufficient elevation to allow of the slide being depressed sufficiently on either side alternately, some 8° or 10°, the illumination remaining fixed. It is necessary that the points of suspension of this slide-holder, when raised or lowered, shall be in the same plane as the objects when mounted upon slides of different thickness. An explanatory figure is given. The plan Dr. Maddox adopted is stated in Dr. Beale's *How to Work*, &c. Slips of cork cut to the necessary angle have been suggested to be placed under the slide at alternate ends—rather a rough and troublesome method. Possibly the inexpensive form of protective stage, lately suggested by Mr. Stewart at the Royal Microscopical Society, for preventing damage to the slide by inexperienced hands, may answer very well. A thin strip of mahogany $1\frac{3}{4}$ in. wide and $3\frac{1}{2}$ to 4 in. long, with a central aperture of about 1 in., has fastened to it, on the upper surface, two strips of wood about $\frac{3}{8}$ in. thick and $1\frac{1}{2}$ in. long, the top of these strips being each covered by a thin strip of brass which projects beyond the wooden strip. Over the end of the brass strips at equal points are stretched two thin india-rubber bands, the slide being passed between and clasped by each of the bands. By attaching with a pivot a strip of brass with a slot to the end of the upper right hand brass strip, and a similar one to the lower left hand end, each having a rather coarse screen with milled head working through the free end of the strip, after centering the object, one could be swung over the slide, the blunt screen point brought, by means of the slot, to a line through the centre of the slide, and the depression made by turning the screw. One image being taken, the screw should be released, the small strip turned aside, and the same plan pursued with the opposite side, care being taken to equalise the turns of the screw. We believe this addition, with care, would meet the difficulty, when the object is far from the centre of the slide. The strips can be turned aside when not needed. The above methods refer to the monocular form of microscope, and are very useful when the stereo. plate-holder is fitted to a strong microscope used in the vertical position, for moderate enlargements. Care is required in mounting the prints, otherwise a pseudoscopic effect will be given to the combined images.

The binocular stereoscopic, or the pseudo-binocular form of microscope, can be used for producing stereo. pictures; but in the ordinary form of the former, where the body tubes are set at an angle, there is a difficulty in attaching the double camera. As Nachet's pseudo-instrument is not used in this country, Stephenson's binocular microscope can be conveniently used with the double camera. In all cases where prisms are used to divide, or secure, two images they should be set near the back lens of the objective, and it should be remembered that there is a considerable diminution in the actinic power of the light.

In this Journal, Feb. 10, 1871, the then Editor, Mr. J. T. Taylor, pointed out a method by which enlarged stereo. images of minute objects could be produced by retaining the lens and object in an immovable position during the whole operation, and, after focussing, shifting only the direction of the light. A photograph of the head of a crane fly was taken by a two inches objective for one picture, and the concave mirror then slightly moved so as to illuminate the object "from a different point in the horizontal line." This must be attended to, the amount of relief in the combined pictures exceeding that furnished by the binocular microscope. Higher powers, as a quarter objective of wide angular aperture, stopped down to furnish sufficient penetration, were used successfully upon *Navicula angulatum*, and Mr. Taylor (see this Journal, page 411, 1877) also found that the images first reflected by proper mirrors, and again reflected at the right distance by total reflection along the two body tubes, set at the necessary position, enabled him to successfully obtain binocular pictures with a one-twelfth objective. This mode of working involves rather more trouble than when producing single pictures, and we fear is not likely to be generally adopted. The stereographs of some of the *diatomaceæ* have a peculiar charm, in their delicacy and crystalline transparency, entirely their own. Dr. Maddox obtained stereo. photographs of some of the *coscinodisci* that when combined resembled crystal inverted saucers; but with portions of *Pleurosigma formosum* and *angulatum* at 3,000 diameters there was always a difficulty to exactly centre the pictures at their necessary displacement. Spicules of *synapta* and the wheel plates of *cheirodota* are excellent objects for the purpose. Some of the *diatomaceæ* form most difficult objects; those of *heliopelta* and *aulacodiscus* were seldom satisfactory, being more or less confused.

For giving objects stereoscopic relief Mr. Furze recommended a plano-convex lens, ¾-in. inch diameter, with central and external stops, each revolving on a separate axis, and an adjustable cap on the top of the lens, with a crystal of herapathite mounted between thin glass, and also a plate of selenite on thin glass to be used when objects were of rather too great density for transmitted light, as thus illuminated they appear as if in relief. (*Trans. Microscopical Society*, 1855.)

Although this applies rather to micrography than to photomicrography, yet with such objects it may be useful, though the time of exposure would be much increased.

The original intention was to complete this series of articles in our last volume, but it was found impossible without condensing detail too much. Some points which have been only incidentally alluded to now remain to be briefly touched on, and a full table furnished of useful references.

Is engraving to become a lost art? Such would appear to be the prospect if there be any foundation for the wail of the *Daily Telegraph*. According to that journal engravers proper are rapidly dying out—done to death by *photogravure* and other photo. "processes." Whether this be so or not, the matter is, after all, one of supply and demand. So long as the productions of the engraver retain their superiority over photographic productions so long will engraving continue to exist; but as soon as photo-engraving is able to compete on equal terms, as regards quality, with the older and more expensive style, so soon will the latter cease to have a *raison d'être*. It would be as reasonable to attempt to shut up railways and return to the old mail-coach system as to expect photo-engravers to study the special interest of the artist of the graver and etching needle.

Our readers will very likely remember Mr. F. Galton—an enthusiast upon the subject of obtaining and tabulating all kinds of data respecting the human frame. Some year or two ago a paper by him was read before the Photographic Society of Great Britain, in which he explained a method he had devised for obtaining an average type of face from superposing a number of images of faces taken to scale, and thus obtaining a single face—a plan which, as our New York contemporary, the *Photographic Times*, aptly observed, was as likely to be successful—may we add useful?—as an attempt to picture a house of average size by printing a poor man's cottage and a Fifth Avenue mansion upon one another on one sheet of paper. Mr. Galton has lately given another stimulus to the production of photographic portraits in the offering of prizes to the amount of five hundred pounds in connection with a plan entailing the production of a number of photographs.

The prizes are given to the one who most successfully fills up his book, the *Record of Family Faculties. The Life-History Album* is a companion volume, "being a Personal Note-book combining the chief advantages of a Diary, Photographic Album, a Register of Height, Weight, and other Anthropometrical Observations and Records of Illnesses." In the former book, not only is every possible detail respecting the competitor's father and mother, grandfather and grandmother, required, but also his father's father's father, father's father's mother, &c., &c.; in the latter his own history only, among which numerous details, including every ailment from teething to toothlessness, he is to place every five years a photograph of himself. The editor has not left even a blank page after the age of seventy-five, so that nonogenarians and centenarians can leave no records for admiring and wondering posterity.

Our contemporary, the *English Mechanic*, lately had some observations to make upon the subject of Dr. Huggins' photographs of the solar corona, taken from the sun while an eclipse was occurring. We described these interesting pictures and the ingenious mode by which they were produced shortly after Dr. Huggins brought them forward. Our contemporary's remarks were based upon the probability of the "rifts" seen in Dr. Huggins' photograph being due to reflection from the backing; and, as they are based upon entire error, thus naturally giving rise to a feeling of annoyance, if not even injury, on that gentleman's part, it may be well here to give the erroneous part of them in the words of the original:—"It is now suspected that the pseudo-coronal structure visible in his negatives may have its origin in reflection from the dark backing of his photographic plates, such backing being painted on in streaks with a brush."

Now, two errors are to be noted here. If our memory serve us right the backing was asphaltum, presumably dissolved. It would, therefore, be quite indifferent how the black varnish was laid on—whether with brush or spatula, or were poured on—the result would be identical. If the whole surface were covered, the backing would be in optical contact, and there would only be a plane surface to reflect from. Secondly: the backing is placed, as most practical photographers know, to prevent reflection, or at least either to reduce it to a minimum or to alter its character so that it should possess no actinic power. Dr. Huggins, it is stated, speaks of laying the varnish on with a spatula, and in view of the great intensity of the light the image would possess this may be a wise precaution. As asphaltum is to a certain extent transparent, reflection might occur from its back surface; still we should almost imagine that in the case in question a pouring on of the varnish would have been simpler, seeing it was not the actual image of the sun itself that was thrown on the plate. But it must be observed that, by adopting the plan he did, the learned astronomer took every possible precaution to avoid that very evil which his photographs are now said to be suspected of displaying.

The fifty-eighth annual exhibition of the Royal Scottish Academy will be opened on Saturday, the 16th instant. Many of the more distinguished members of the R.S.A. and contributors to its annual displays utilise photography in their artistic labours, and are not afraid to avow their indebtedness to our art-science.

Apropos of the subject of the hygrometric condition of the atmosphere lately discussed by us, an account is to hand of a most wonderful instrument, a supply of which it will be well for the meteorological instrument makers to procure. Baron Maclay lately read a paper before an antipodeal society upon the *Barometio araucano*, which had been shown to him by Captain C. de Amezega, of the Italian corvette *Curaciolo*, who informed him that the natives of the Chiloe Islands used it as a kind of barometer to foretell the approach of dry or wet weather. Some continental writers have strange ideas about crustaceans, a celebrated Frenchman once terming a lobster "the cardinal of the deep." The crustacean in this case is a crab—the *Barometio araucano*—and the Baron was informed that its shell, which under normal atmospheric conditions is white, possesses the wonderful property of becoming dotted with red spots upon the approach of moisture, increasing in number and size with the increase of humidity, until during the wet season it becomes completely red ! That the Baron believed his informant is evident.

A new thermometer, of singular properties, has been devised by M. Latschinoff. Ordinary mercurial thermometers, as our readers are aware, act by the dilatation of the mercury exceeding that of the glass, and so upon heat being applied the mercury rises in the tube as its bulk is increased, that being the only available exit. The new thermometer has an ebonite bulb which expands so largely by heat that the mercury cannot keep pace with it. The consequence is that, when heat is applied, instead of the mercurial column rising it falls; hence, with M. Latschinoff's thermometer, when we say the thermometer is very low we mean it is warm, and when we see the mercury rising we know the temperature is falling. To say the least of it, this would be very confusing; but we do not think it very likely that, with so uncertain a substance as ebonite, these new instruments are likely to come into use.

According to *La Nature*, for some years a large number of articles, such as *porte-monnaies*, travelling bags, &c., have been made of crocodile and serpent skins, or those of other more or less rare animals, and it has been difficult to procure genuine skins in sufficient quantity to meet the consumption. Accordingly they have been replaced by imitations. Our contemporary quotes the *Scientific American* as follows to show how photography has assisted in the matter:—"An alligator, or boa, or seal skin is photographed in such a way as to give an exact reproduction of the chequering and mottling that characterise each kind of skin. This photograph is used to produce, by means of a galvanoplastic process for example, a metallic plate which, passed between the cylinders of a rolling-press with any ordinary leather whatever, gives it the exact appearance of the leather it is desired to imitate." *La Nature* goes on to say that it reproduces the text of the American journal, but it does not well understand the intervention of photography—at least that the photoglyptic processes should not be used. According to its editor it appears that the operation could be performed directly by the aid of galvanoplastic moulding.

The same journal contains an account of a small portable electric light arrangement, worked by a battery of four elements, modelled on the Poggendorff pile, the whole being the invention of M. Radiguet. The elements are so constructed as to be easily withdrawn, and are acted on respectively by bisulphate of potash and acid bichromate of potash. Many similar *apparata* are made in this country, but this particular one seems to be especially compact and handy. We have no details as to its cost.

It is very reprehensible that the historical portrait department of the photographs exhibited in the Patent Museum at South Kensington does not receive a little more attention from those in authority. One looks upon the facial lineaments of really great men, many of whom have long since passed away, with profound interest. It is not by any means pleasant to find that these museum portraits show strong indications of fading; and, seeing that a photographer of the eminence of Colonel Stuart Wortley is curator of this national collection, it would be extremely desirable if Colonel Wortley would exert his influence—first, in having the already existing portraits reproduced in an imperishable material, such as carbon ; and, secondly, in greatly adding to their number.

Referring to the comet Pons-Brooks, the Rev. T. E. Espin, B.A., F.R.A.S., Observer to the Liverpool Astronomical Society, writes as follows:—The comet was detected by Brooks, in America, on September 1st of last year, and for a long time remained an insignificant object. The path it was travelling speedily showed that it was identical with the comet of Pons, observed in 1812. Up to the end of November it appeared as a bright nucleus with a circular haze, and on December 5th it showed a short tail from the circular haze. During the following evenings it swept across the Milky Way, and on December 24th was close to, but a little inferior in brightness to, the second magnitude star Epsilon Sygni. On this evening I succeeded in photographing it with an exposure of fifty-three minutes. On the negation it appeared as a circular haze with no tail. I did not catch sight of it again till the moonlight night of January 5th, when it was observed by me and two other members of the Liverpool Astronomical Society with the five-inch refractor seven feet long. At this time the tail had increased, and the brightness of the comet was above a second magnitude star. The tail could be traced some five degrees, in spite of the moonlight. When the moon had passed out of the way the comet was much fainter, and on January 19th and 20th was comparatively an insignificant object. Two other points must be noticed. The spectrum of the comet in December corresponded with the spectrum of alcohol, and there can be little doubt that the path is identical with that of a stream of meteors which radiate from Draco in December.

PHOTOGRAPHY AND PHILOLOGY.

It might be thought that these two subjects had little in common ; but we promise our readers that if they will spend an hour or two in looking through the first part of the *New English Dictionary*, just published under the auspices of the Philological Society, they will find in its pages a fund of interest, if not of instruction, in connection with matters photographic alone. We all know the story of the old lady who found a dictionary very entertaining reading, though she disliked the frequent change of subject ; but even that standard joke could not be passed upon the present publication, some words taking a full share of a page to elucidate their meaning, and many upwards of a column.

We are sanguine that any photographer who takes up the work will agree with Théophile Gaultier in looking upon the perusal of a dictionary as a pleasant mode of whiling away time. A large folio volume of three hundred and fifty pages—to which upwards of thirteen hundred persons have contributed, together with a whole army of sub-editors and the aid of numerous specialists, technical, artistic, and otherwise—ought to be very complete. And complete this wonderful tome is, with a total of 8,365 words treated, as against 4,162 and 4,198 respectively in Webster's or Ogilvie's lexicons, hitherto looked upon as the most comprehensive published in our language.

One remarkable feature in the present work is the great scope of the authorities referred to, embracing references to writers in the fourteenth century down to the daily newspapers of the present period. Thus, we turn to the word "Albumenizer," and we find, after the derivation, the meaning, "One who albumenises," with a reference, "1879, *Daily Telegraph*, 25th Oct (advertisement) 'Albumenizers —The Imperial Company have vacancies for several first-class hands.'" Now, we take it that a firm of photographic albumenisers never had their names put in the text of a dictionary before, nor did the *Daily Telegraph* ever get quoted in one previously.

We find "Albumen" (also spelt in a cross reference with "i" for "e") fully described, and "Albumenize" also, the latter word being referred to photography; while under "Albumenized" we have a reference to the *Quarterly Review* of 1868, which speaks of the number of eggs consumed in the production of albumenised paper. What, we wonder, would the reviewer have to say to the consumption of the present day for photographic use alone?

We need not go further than the same page to find "Album," the gradual change in the meaning of the word being shown through a series of words, till at the last we reach—"A book for reception of photographic *cartes* and views, or of postage stamps, crests, or other things which are collected and preserved." This our readers will hold with us to be a rather restricted view. The plan of this *Dictionary* was first devised in 1857, and, possibly, the meaning was given to it at an early period, when the *carte* reigned lord paramount in photography, and when the "cabinet," which now bids fair to overthrow its sovereignty, was not. There is an amusing excerpt from Charles Lamb, who writes in 1829 of fleeing to escape the "albumean" persecution. We can imagine his feelings if he had lived late in the Victorian era, and been pestered for his *carte*. At a still later period he might have borne the nuisance with equanimity, as he would then, no doubt, have been asked to "sit," and offered a premium for doing so.

Our readers may remember some months ago our noting the editor's request for references for the word "Ambrotype," and our suggesting the perusal of photographic literature, where it once abounded. We note that the word occurs with references to *Notes and Queries* (1855), *The Autocrat of the Breakfast Table* (1858), and the *Century Magazine* of 1882. We think far better suggestive extracts might have been supplied from the source we indicated. The word is described as "the name given in the United States to a photograph on glass, in which the lights are produced by the silver, and the shades by a dark background showing through." The derivation is given from a Greek word signifying "immortal," or, perhaps, "Amber + Type." We fail to find a photographic reference to the photographic term "alabastrine," its nearest relative, and, perhaps, it is as well that all reference to so fugitive and almost forgotten a style of photography should be avoided.

The editor, however, has not left out "Actinium;" but he shrewdly terms it a "supposed" chemical element, "* * * so called because of the action of light upon its salts." The date of its discovery is given as 1881; yet no one but its discoverer appears to have seen the substance, and, as some years have now elapsed, we have little hope of the old photographic *répertoire* being increased by the addition of another light-sensitive element.

"Actinism" is neatly treated; but the references are not new, and refer rather to the older conception of the functions of solar radiations, the extracts given being behind the time. Thus, in 1844, Mr. Hunt speaks of the "relative quantity of the active chemical principle" in a prismatic analysis of the sun's rays, while the latest reference is 1862—Mr. Patterson's.

It must not, however, be thought that we are, in thus speaking, finding fault. The *Dictionary* is not a cyclopœdia, and words rather than things are described. The change of the former is slow, and it is a positive advantage to have them registered. The theories of yesterday go in the waste-paper basket of today, and their symbols only do we wish to preserve in a dictionary.

We will finish our excursion into the realms of science and philology by referring to the word "Alcohol," which teems with interesting data about the present and past meaning of the word. Few who speak so freely of alcohol in the present day have any idea that it is a contraction for "alcohol of wine," so formed from the original meaning by a process of extension. Primarily used to indicate the fine powder employed by Eastern beauties to stain their eyelids with, it gradually was employed to signify any fine powder produced by trituration or (and more especially) sublimation. Even so late as 1812 we have Sir Humphrey Davy speaking of the "alcohol of sulphur," alcohol and essence then being evidently convertible terms. The alcohol of wine is an easy transition.

We could wish to follow the editor in his interesting remarks upon many other photographic words ("Aberration," "Achromatic," "Alum," "Acid," and many others), but space forbids; and we can only recommend our readers to dip for themselves into this interesting "well of English [defiled and] undefiled."

ACTINIC FORCE *VERSUS* COLOUR.

Mr. W. H. Harrison stated, in his remarks on my dark room lamp, that he thought I had made a mistake in using white as a substratum. There is no doubt that if I had used orange the light would have been safer, but it would have been at the cost of decreased luminous power. He further speaks of the blue rays only requiring to be absorbed; but this way of putting it often leads to mistakes, because a gelatino-bromide film is sensitive to all the colours of the spectrum. What is actinic force? Capt. Abney and others have been photographing the ultra-red rays beyond visible light and have found it there; and I wish to suggest whether it would not be better to leave off calling the rays at the violet end of the spectrum "actinic rays" and those at the red end "heat rays," because in both cases the names are misapplied.

I purpose proving that actinic force is a power quite distinct from colour—indeed, it is evidently a counterforce to it. (By colour I mean the different wave-lengths into which white light is divided by the prism.) If we throw the spectrum on to a gelatino-bromide film we find that *the prism has not analysed actinic force.* True it passes most readily with the blue and violet rays, but it does not pass solely with them. In the yellow (which does not contain any of the so-called "actinic rays"), and even in the red, we find actinic force passing through the prism. Again: if we place a piece of ruby glass (which has been proved by the spectroscope not to transmit any green or blue rays) before a gelatino-bromide plate, and expose them to candle light, we shall find that we have not stopped actinic force from passing to the plate. Indeed, with plates sensitive to the ultra red rays we shall not (theoretically) be able to have a lamp really safe for dark-room illumination, because the plates are sensitive to a point beyond visible light. This proves that actinic force must be a power in light quite distinct from the luminous rays, which are white light divided by the prism into colours of different wave-lengths, and which we know as the colours of the spectrum.

And now comes the question—If actinic force be distinct from luminous light, why will it pass more readily through blue than red glass? I believe the reason is that it is governed by the power of the different wave-lengths of the various colours of the spectrum. The shorter the wave-length the greater the amount of actinic force; increase the length of the wave and we have a corresponding decrease of actinic power. We know that those at the red end of the spectrum are the longest, and of course the longer the wave-length *the greater must be the force which makes it so;* so that we have here a counter force to actinic power. This will explain why light has more power on a sensitive plate when passed through blue than when passed through red glass. In the latter case we have put the strongest single force that there is in the luminous rays between the actinic force and the plate. The red glass has brought the various wave-lengths of the white light all to one long length—I ought rather to say nearly to one length, because the spectroscope would probably show that the red glass was not a pure colour, and that it contained a trace of orange, &c. In coloured glass we have an equally-distributed force throughout the substance which acts as a sort of buffer stop to actinic force, the strength of the buffer depending on the wave-length of the colour of the glass used.

Mr. W. E. Debenham showed some time since that by putting two mediums—one green and one yellow—he got a safer light than with red alone; in other words, he had put a stronger power between the actinic force and the film. With the yellow medium he had the greatest luminous power, the wave-length of which was comparatively long; with the green he had a colour the least injurious to the eyesight, though of less wave-length. The combined wave-lengths of the two, however, would be more than that of the red alone, and in consequence the light was safer.

We thus see that light consists of two distinct forces; whether the one or the other is the stronger depends on the substance which reflects or the medium that transmits light. If we have a substance which either reflects or transmits a colour of a short wave-length (such as blue or violet) we get great actinic force; but, if the colour reflected or transmitted have a long wave-length, the increased strength of it will act as a stronger force than the actinic, and the latter will only be able to affect the silver haloid to a small extent.

There is one more point which requires to be referred to, namely, that some colours when reflected have a less restraining power on actinic force than when transmitted. My attention has been called to Mr. Sawyer's experiments on reflected light, and also to his paper on the subject read at the meeting of the Photographic Society of Great Britain in May last. I am pleased to see that his experiments quite corroborate what I stated in my article describing my reflecting lamp, viz., that orange by reflected light gives nearly as dense a deposit on a film as the blue, &c. Since I found that Mr. Macdougald thought I must have made some mistake I have again gone into the matter, and the only explanation I can give for it is this: some substances reflect the complementary colour, or nearly so, to what they transmit. For instance: gold leaf is almost yellow by reflected, but is green by transmitted, light. Aniline dyes have also this peculiarity. The colour known as "violet of methylaniline" is yellow by reflected, but violet by transmitted, light; and the red aniline dye is yellowish-green by reflected, but red by transmitted, light. I do not know how the orange colour is obtained in woollen materials; but if it were an aniline dye the complementary colour to the orange would be blue. As a portion of the light would be transmitted through a portion of the substance and partially reflected the apparent orange colour would be of a compound nature, part of which would probably be blue; and as this colour has a short wave-length, it would account for the increase of actinic power when reflected from an orange surface compared to transmitted light of the same colour.

There is another point that has an important bearing on the subject, which is that white light is made by compounding together all the colours of the spectrum; but it may also be produced by two colours only, and the eye is not able to distinguish whether the white is a compound of the whole spectrum or whether it consists (as proved by prismatic analysis) of only two colours. Neither will it tell the difference between a compound blue, containing nearly one-half the colours of the whole spectrum, and the pure spectrum blue of the same apparent shade. Now it is most probable that the effect on a sensitive film would be different in these cases, because the combined wave-lengths would be different. But the subject of reflected light and its action on a sensitive film requires to be examined thoroughly. It is a matter that has hardly yet been raised, and is one which I believe will lead to most important results in its bearings on practical photography.

There is another important point about "actinic force" *versus* "wave force" (or, as it is usually and, I think, wrongly described, "actinic rays" *versus* "heat rays"), and that is that if we heat a metal to a red heat we get red light—the longest wave force and the least actinic force; but if we heat it more—say, to a white heat—the additional wave-lengths are shorter and there is a corresponding increase of actinic force. So we see *that heat generates actinic force*—and not only that, but the increased heat has expanded the metal; thus actinic force and expansion go together, but if the heat act on the metal for any length of time we get a decomposition of the metal, which would be a chemical action. And this is another link in proof of my theory that the action of light or, rather, actinic force on a silver haloid is first an expansive force, or, in other words, it expands the particles of silver bromide which burst the thin cells of the gelatine or collodion that surround them, and thereby allows the developer to act on the particles; but, where the light has not acted, the gelatine film surrounding the particles protects them from the developer. If the action of light be continued we get the decomposition of the silver haloid; that is, the chemical action or reduction to a sub-haloid. This, I believe, is what we know as the reversed action of light, which is identical with the action of the light on a daguerreotype before development by mercury vapour, and the reduction to a sub-chloride of silver chloride in silver printing. If it be not so, how can we explain why light can act on a particle of silver bromide tightly enclosed in a casing of gelatine with as much effect in a minute part of a second as it does on a similar particle atttached to a daguerreotype plate (where it is quite unenclosed) with several minutes' exposure?

We know that the wave-lengths of the violet are shorter than the blue; we would, therefore, expect to obtain greater actinic force from a violet than a blue surface. But the glasses of which our lenses are made absorb an amount of actinic force; if we use quartz lenses the violet rays are less powerful to withstand actinic force. But there is another reason: violet surfaces are generally a compound of blue and red, and the long waves of the red would decrease the actinic power reflected from the surface.

We know that a gelatine plate giving a red or orange colour by transmitted light is much slower than one giving blue. This would be certain, because the actinic force passing through the gelatine to the various particles of silver bromide meets with less opposing force from the short wave-lengths of the blue than it does with the long wave-lengths of the red or orange. The question has just struck me:—Would not the pocket spectroscope help us immensely when preparing an emulsion, by telling us (by the spectrum given by the emulsion by transmitted light) exactly the point when it has reached a certain point of sensitiveness? At present we either trust to boiling a certain length of time under circumstances perhaps never twice exactly alike, or we trust to the eye to tell us by the change in the colour; but in this case we have no certain guide, because we have no fixed colour with which to compare it. In the preparation of Bessemer steel, by the employment of the spectroscope the exact moment of the completion of the process is determined; and I think the instrument will be equally useful in the preparation of emulsion.

But the fact of the blue emulsion being the more rapid is also caused by the gelatine being more decomposed by boiling or by the addition of ammonia; so that prolonged emulsification has a double action—it weakens the gelatine, and allows the particles of the silver haloid in expanding to more readily burst the gelatine cells. It also alters the nature of the gelatine, and causes it to transmit blue instead of red light. That it is so, and that boiling does not cause a chemical action between the silver bromide and the gelatine, is proved by boiling—

Gelatine	200 grains,
Ammonia	1 ounce,
Water	9 ounces,

for one hour; then, if we add the silver bromide, we at once obtain an emulsion giving the blue-grey colour by transmitted light. I am quite convinced that this is the best way of preparing an emulsion, both from a theoretical and practical point of view, and one which will give the most certain results when successive batches of emulsion have to be made of the same rapidity.

HERBERT S. STARNES.

STANNOTYPE.

No. I.

MOST of our readers have, no doubt, some sort of idea of the principles, at least, of the stannotype process which has received mention in many ways recently; but there are probably few who are at all intimately acquainted with its details. As the process is one which is likely to prove of great utility in certain branches of photography, we propose in the course of a few articles to give a description of its practical working.

Stannotype is, briefly, a simplified method of producing the actual printing surface from which the well-known "Woodburytype" prints are made; for the process which bears the name is confined to the production of the "mould," the subsequent printing being in every respect identical with Woodburytype. But the modification in the preparation of the "mould" is of sufficient importance to remove this style of printing from its hitherto existing state, as a method of purely commercial practice on a large scale, and to bring it within the reach of any photographer who may wish to produce more than a very few copies from his negatives. The process is not one that recommends itself—nor is it so intended—as a substitute for silver printing, or for work on an extremely small scale; for the simple reason that the various operations involved in the production of the printing mould are scarcely recompensed by the return brought by a dozen or so of prints. But, on the other hand, the printing mould once secured the prints are obtained by the dozen, the score, the hundred, or the thousand at a merely nominal cost, and with a rapidity that cannot be excelled by any process, photographic or photo-mechanical, while the results are indistinguishable from the best silver prints.

There may be some of our readers who are entirely ignorant of the nature of stannotype; for their benefit, therefore, we may give a brief outline of the Woodburytype process and the subsequent modifications which have been made upon it. Like the majority of the photo-mechanical methods of printing it is based upon the employment of a surface of bichromated gelatine. This is prepared in the same manner as for ordinary "carbon tissue;" but the layer of gelatine is many times thicker, and contains a much smaller quantity of colouring matter. The first stage in the process consists in the exposure under an ordinary negative of a piece of this special tissue. Upon development in the ordinary manner of a carbon print—though the operation is much more prolonged—a relief is produced in insoluble gelatine, from which, when dried, a counter-relief is made by heavy pressure in contact with a plate of soft metal under the hydraulic press, this latter relief being the actual printing mould.

The printing is performed by means of a gelatine ink which, when poured upon the mould and overlaid with paper, is submitted to equable pressure. The surplus ink is forced away to the edges of the mould, leaving the hollows filled, and thus a cast in coloured gelatine is left adherent to the paper, which, as soon as the ink has set, is detached from the mould, and forms when dried the finished print.

The necessity for the hydraulic press limited the utility of the Woodbury process, and for many years past attempts have been made to dispense with its services, but for a long time without practical success. Mr. Woodbury himself, however, some three or four years ago, devised a plan by which the gelatine relief, instead of being pressed into a plate of metal under the hydraulic press, was "faced" with tinfoil, and upon the latter an electro deposit of copper was made, while this, again, was backed up with resinous matter to give it solidity. The triple layer of tinfoil, copper, and resin being detached from the original gelatine surface formed the printing mould.

Here, however, though the hydraulic press was dispensed with, the introduction of the electrotyping proved an obstacle, and this modification of the process scarcely advanced it much in popularity. Very shortly, however, Mr. Woodbury further simplified the method of producing the printing surface, and his process of stannotype has secured for him several recognitions, including the progress medal of the Photographic Society of Great Britain, as well as a medal at the last exhibition of the same society.

In this process the gelatine relief is made in the same manner as before, except that a *positive* is employed instead of a negative in its production. A relief in reverse is thus obtained, and this is faced with tinfoil and employed as the actual printing surface. The tinfoil merely serves the purpose of preventing the warm gelatinous ink from acting upon the surface of the relief, which, though insoluble, is capable of absorbing moisture, and thus losing its sharpness as well as being liable to damage. The mould thus produced is printed from in the same manner as the ordinary Woodburytype.

In succeeding articles we shall describe minutely the different steps in the production of the stannotype mould, and its subsequent use as a printing-block.

A THERMOMETER FOR THE DARK ROOM.

AT various periods since the invention of the thermometer endeavours have been made to have its variations registered by means of an index which, like the dial and hands of a clock, could be seen at a glance. In more recent years several ingenious devices have been brought to bear upon the problem with a view to its effective solution. So much had been done in this direction with regard to the barometer, as evidenced by the "wheel" and "aneroid" instruments, why could not some similar means be discovered by which the indications of the thermometer also might be shown by means of a finger?

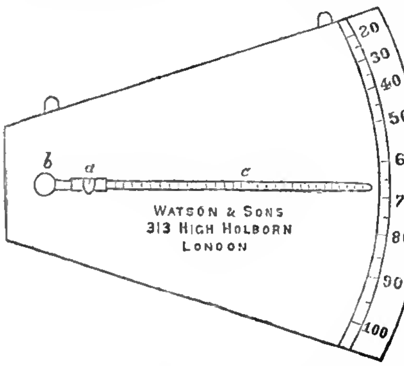
This is a question in which photographers are much interested. For, whereas in a room lighted by the full blaze of daylight in midsummer one can only note the indications of an ordinary thermometer by peering somewhat closely into it, in a subdued light this is effected with increasing difficulty; while in the dark room it becomes quite impossible to note the temperature at all by means of a thermometer of the usual class.

Among the patents obtained this year one has been granted for an invention which supplies this desideratum in an excellent manner—so excellent, indeed, as to enable the thermometric indications to be seen with the greatest plainness at a distance of several yards. Previous to giving details of Messrs. Watson and Sons' new indicating thermometer, it may be useful and interesting to briefly describe the means hitherto employed for a similar purpose.

If a strip of sheet brass be soldered or riveted to a similar strip of steel in such a manner as to form a compound laminated band, one side of which is steel and the other brass, such a band will never remain straight during changing temperature, but will curve itself either to one side or the other. The ratio of expansion of brass being greater than that of steel, the former metal on the application of heat would expand and become slightly elongated; but, as it cannot do this in consequence of its attachment to the steel, in its endeavours to obey the law of nature it forces the steel round into the inner side of a curve, the opposite condition taking place when the cold is in the ascendant. It is in consequence of this law that chronometers are compensated for heat and cold; and it is not difficult to understand in what way the same principle may be applied to actuate a hand or pointer by which thermometric changes can be indicated. There are certain inherent difficulties connected with this system which, in addition to the expense of carrying it into practical form, have militated against its popular or even successful introduction.

In Messrs. Watson and Sons' thermometer the ordinary mercurial bulb and capillary tube system is the one adopted. This tube is, like the thermometers of the better class, graduated upon itself by being etched with fluoric acid, so that to that extent the tube is a graduated thermometer complete in itself, and to read it off correctly necessitates the close introspection to which we have already alluded. Here, now, comes in the improvement:—Grasped by a short tubular brass collar capable of sliding tightly upon the thermometric tube for purposes of adjustment, and which brass collar is pivoted, the thermometer is poised or swung like a long lever with a short counterpoise. By the rising and falling of the mercury in the tube, the centre of gravity changes its place and disturbs the equipoise of the tube, the upper end of which thus sweeps round a radius, of which the pivot in the brass collar is the centre.

The annexed diagram explains the whole arrangement better than any verbal description. The tube is shown balanced at *a*, near the bulb *b*, the upper end of the tube *c* acting as the indicator.



As the tube is white, owing to the enamelled glass of which one side is formed, and as the background over which it moves is black, it is evident that the indications can be seen with great ease. Those who are prone to jocularity will not fail to observe that *this* thermometer, unlike others, rises with cold and falls with heat. The name by which it is intended to be known is the "Patent Balance Thermometer.'

When for scientific purposes a more accurate reading of the temperature is required than that afforded by the index, it can immediately be obtained by reference to the graduated tube itself. This thermometer cannot fail to prove of great utility for many purposes in addition to its use in the photographer's dark room.

SOCIETY OF ARTS.

On Monday evening last, the 28th inst., the first of a series of Cantor lectures was given by Mr. T. Bolas, F.C.S., at the Society of Arts, John-street, Adelphi, the subject being *Recent Improvements in Photo-Mechanical Printing Methods.*

This is the second course of lectures which Mr. Bolas has given on the same subject, the first having been delivered some five years ago. The lecture was well attended, the large hall of the Society of Arts being quite full. Mr. B. F. Cobb, Vice-President of the Society of Arts, was in the chair, and briefly introduced the lecturer.

Recent Improvements in Photo-Mechanical Printing Methods.

Mr. Bolas commenced his remarks by saying that the present condition of the various institutions which went to make up society was greatly due to the influence of the printing-press, and that in the work of the printing-press the camera was coming to take a larger and larger share. Various methods by which a photograph could be printed mechanically had been described by him some years ago; but since that period great progress had been made. He pointed out that almost all the methods of printing which were mechanical involved the use of an ink of somewhat the same nature as that used for letterpress printing—that is to say, one in which carbon is the basis—and that, therefore, they had the enormous advantage of giving prints which were permanent—a thing which no process giving a silver image did.

All mechanical printing processes, previous to the present date, depended for their working on the fact that, if gelatine were treated with a solution of bichromate of potassium, it retained its solubility only so long as light was not allowed to act upon it, whereas when it was effected by light it became insoluble. Lately, however, Dr. Eder had made a discovery which might lead to an entirely new direction of working. This was that if gelatine be treated with ferricyanide of potassium an insoluble compound results, which, however, becomes soluble when light acts upon it. [A complete demonstration of the various modifications of the Woodbury process followed these remarks.]

A portion of slightly pigmented, bichromated gelatine tissue was exposed under a negative. This was then squeegeed into a piece of glass, and was developed by pouring hot water on it, the image of the plate being meantime thrown on a screen by a lantern, so that all might see the operation. By this means a gelatine relief was gained.

A similar relief, which had been previously prepared and dried, was now taken, and being placed in contact with a block of type metal in the hydraulic press of Mr. George Smith, a mould was obtained. Into this mould there was poured some liquid pigmented gelatine, a sheet of paper was placed against it, and the excess being squeezed out in a press, a reverse mould was obtained by the time the gelatine had set. This was the final print, requiring only to be dried first —in practice being, as a rule, treated with alum to harden the gelatine.

The only objection to this process lay in the necessity of using a hydraulic press, which is a somewhat cumbersome piece of apparatus. To overcome this Mr. Woodbury invented an improved process, which was demonstrated. The gelatine relief is prepared exactly as before, but instead of a metal block being impressed with it, there is brought into contact with the relief a sheet of tinfoil. The two are pressed together through a rolling-press, some elastic material being placed behind the tinfoil. By this means the tinfoil took precisely the form of the relief. Copper was now deposited by electricity on the tinfoil to impart to it somewhat more strength, and on to this was poured some resinous composition, whereby the tinfoil and copper mould became attached to a flat glass or metal plate. This mould was used precisely as the type metal one was. This was the first stannotype process.

Both the original Woodbury and the first stannotype processes had worked excellently, and yet the development of the process had not been so great as the lecturer had five years since supposed it would be. The necessity in the first process for a hydraulic press, and in the second for an electrotyping apparatus, had prevented its being adopted as generally as might have been anticipated.

Mr. Woodbury's latest stannotype process appeared likely to popularise the method of printing by pigments to a very great extent, as by it no special apparatus was required. This process was so contrived that the gelatine relief itself was used in the mould, the relief being in this case obtained from a positive, not a negative. After it was dry tinfoil was pressed into it as before, and this mould was used at once, the only object of the tinfoil being, in fact, to prevent the liquid gelatine solution used in forming the prints from acting on the relief. The tinfoil might be nickel or steel-faced. If the tinfoil showed signs of wearing out, it could be stripped off and new tinfoil might be applied.

An application of Woodburytype to the water-marking of paper was described and demonstrated.

To show the influence which pressure has in rendering paper transparent a half-crown was pressed against a piece of paper folded in eight, fifteen tons' pressure being applied. On each of the eight pieces of paper there was a distinct mark of the coin. It was evident that if a Woodbury relief took the place of the coin any design which was on the relief would be transferred to the paper. Several very interesting examples of water-marks so produced were found around, and amongst others was a most curious one. In this a five-pound note had been caused to reproduce in negative its water-mark by simple pressure, the difference of thickness of the paper at the water-mark and at other portions affording sufficient relief for this.

Mr. Bolas said that great as would probably be the application of the latest Woodbury process which had just been demonstrated, he believed there was a still greater development to be looked for from processes in which the Woodbury relief was converted into line and stipple. This would be demonstrated at the next lecture.

A number of lantern slides produced by the Woodbury process were exhibited after the lecture, the lantern which was used being of novel construction and worthy of notice. One half of the condenser was in its usual position. Next it, and placed at an angle of 45°, so as to cast the beam of light issuing from this half of the condenser upwards was a mirror. Immediately above this was the other lens of the condenser. The slide to be exhibited was laid horizontally on this. It was by this means that the development of the Woodbury transparency could easily be shown on the screen. Above the slide was the objective, and above that again a reflecting prism to change the vertical direction of the rays again into a horizontal one. By revolving the prism the position of the image on the screen could be altered without shifting the position of the lantern.

ON THE CAUSE OF THE SENSITIVENESS OF GELATINE EMULSION AS COMPARED WITH COLLODION EMULSION.

UNDER the above title Mr. E. Howard Farmer has published in THE BRITISH JOURNAL OF PHOTOGRAPHY an interesting study which contains many new observations, but, at the same time, gives expression to many different hypotheses that are untenable after my experiments which were published last year, and with which Mr. Farmer appears to be unacquainted.

I mention, first, a new fact observed by Mr. Farmer—that collodion emulsion is rendered more sensitive by boiling. He boiled a collodion emulsion from half-an-hour to two hours (in connection with a so-called back-flow cooler), and found that its sensitiveness was thereby doubled and its intensity considerably increased. Certainly the sensitiveness attained was merely one-thirty-second part of that of a gelatine emulsion boiled for only one hour. Still the fact is new that collodion emulsion gains somewhat, even if not much, in sensitiveness through boiling. I was *not* able to detect any such increase of sensitiveness when I kept a firmly-closed bottle of collodion emulsion in a water bath of 30° R. for a whole day. The temperature may have been just too low to produce the required effect. Mr. Farmer further precipitated bromide of silver from a very thin, boiled gelatine emulsion, and mixed one portion of it with gelatine and the other with collodion. Here he observed, like me, that the mixing of the latter was extremely difficult. The collodion emulsion proved much less sensitive than the gelatine emulsion, although both contained the same bromide of silver. These results do not coincide with mine. By using glacial acetic-alcoholic collodion I obtained plates which were only a little behind the gelatine plates in sensitiveness. I attribute the slight sensibility obtained by Mr. Farmer to the circumstance of his bromide of silver being too coarse in the grain. Such bromide of silver distributes itself very finely in gelatine, but in collodion it remains as coarse in the grain as at the commencement. I cannot, therefore, subscribe to the view that the sensitiveness depends upon the film (gelatine or collodion); in fact, gelatine has but a very slight effect as a sensitiser.

Neither is the strong developer the cause of the great sensitiveness, since, as I have already proved, one can render collodion plates also suitable for the strong developer by a coating of gelatine; yet, notwithstanding, they remain far behind gelatine plates in sensitiveness. Further: Mr. Farmer's idea that bromide of silver forms an organic compound with gelatine is not proved. *The difference in sensitiveness between gelatine emulsion and collodion emulsion rests upon this*—that *in the two emulsions very different kinds of bromide of silver are contained.*

By my spectroscopic experiments last year I succeeded in establishing that there are two modifications of bromide of silver—that precipitated from aqueous solutions and that precipitated from alcoholic solutions. The first I called, on account of the position of its maximum sensitiveness to the sun's spectrum (length of wave, 450), "sensitive to blue;" and the other, on the same principle, "sensitive to indigo," because the maximum of its sensitiveness lies in indigo by length of wave 438—410.

It makes no difference whether the aqueous or alcoholic fluid in which the bromide of silver is produced consists of gelatine or collodion; whether the precipitation be undertaken with excess of soluble bromide or of the silver salt; whether it take place in the cold or in heat; or whether the bromide of silver is treated with ammonia, is cooked or is not cooked. The only condition is that solutions be used for the precipitation of the bromide of silver sensitive to indigo, which are prepared by means of almost absolute alcohol (96°). From aqueous-alcoholic solutions bromide of silver sensitive to blue also is precipitated, as by Mr. Henderson's process. Some people may object that these spectral differences are not sufficient to found the assumption of the existence of two different modifications. To these I would answer that these two modifications are not only distinguished from one another by their different spectral sensitiveness, but are also determined by other and not less characteristic properties, so that no doubt can prevail respecting their nature as quite different modifications of the same substance. Five of these reasons follow:—

1. *The Unequal Distribution in Gelatine Solution as Compared with Collodion.*—If one prepare a solution of three grammes of bromide of ammonium in 100 c.c. of alcohol, and to this add five grammes of nitrate of silver dissolved by boiling in ten c.c. of alcohol of 86°, one obtains a curdy deposit in no respect distinguishable from that precipitated from an aqueous solution under like circumstances. Now, if both deposits be washed—the one with alcohol and the other with water—one obtains when dried a coarsely-granulated mass, which, in order to be tested photographically, must be distributed or divided by being shaken up with a collodion or a gelatine solution. Here a very remarkable difference is observable. *The bromide of silver precipitated from alcohol does not distribute itself in the gelatine solution at all, while that precipitated with water, on the contrary, does so with ease.* Both substances behave in exactly the opposite way towards collodion. Here the bromide of silver precipitated with alcohol distributes itself beautifully, and that precipitated from water very badly. The distribution of the latter in collodion, however, succeeded so far as to allow of the comparative experiments mentioned above being established; whilst, on the other hand, all attempts to distribute bromide of silver, precipitated from alcohol, in gelatine solutions failed. Another difference between the two modifications is—

2. *The Unequal Susceptibility of Reduction. The Bromide of Silver Sensitive to Blue is much more Difficult to Reduce to the Metallic State than that Sensitive to Indigo.*—If a "chemical" developer be poured upon a bromide-of-silver collodion plate and upon a bromide-of-silver gelatine plate the collodion plate becomes rapidly blackened, accompanied by reduction of the bromide of silver, while the change in the gelatine plate is very slow. For this reason much stronger *chemical* developers may be used for gelatine plates than for collodion plates. (See also under 3 below.) The explanation that the collodion film is much more easily penetrated than gelatine by fluid agents is untenable, since the two sorts of bromide of silver exhibit this same difference when in the same medium (viz., collodio-gelatine). A further difference is—

3. *The Unequal Behaviour towards Chemical and Optical Sensitisers.*—It is acknowledged that there are substances which, by their power of combining with one of the constituents of a substance sensitive to light set free by exposure to light, very considerably promote the action of the light. As I have already made known, this action of the sensitiser or accelerator shows itself very conspicuously with collodio-bromide of silver, but much less so, however, with gelatino-bromide of silver. Here a secondary action upon the gelatine film may partly bear the blame. Yet, in my experiments with collodio-gelatine, where no such secondary action was present, the slightness of the action of chemical and, still more so, of the optical sensitisers was also manifested. The favourable effect of chemical sensitisers upon the bromide of silver sensitive to blue has as yet only been proved in the case of nitrate of silver with pyrogallic acid and of optical sensitisers of fuchsine. A still further difference is—

4. *The Unequal Behaviour towards the Photographic Developer. The Exposed Bromide of Silver, which is Sensitive to Blue, is very Considerably (at least fifteen times) more Sensitive to the Chemical (Alkaline) Developer than to the Physical (Acid) Developer.*—The bromide of silver which is sensitive to indigo is, on the other hand, at most but three times as sensitive to the chemical as to the physical developer. This difference is the more surprising from a photographic point of view, as here the astonishing sensitiveness of the new gelatine plates, as compared with all other preparations, is only conspicuous when the plate is treated with the *chemical* developer after exposure in the camera. Towards the *physical* developer the bromide of silver sensitive to blue does not show itself to be more sensitive than the bromide of silver sensitive to indigo. In conclusion: both modifications show—

5. *An Unequal Behaviour when Heated. The Bromide of Silver Sensitive to Blue, and Prepared with Excess of Bromide, is very Considerably Increased in Sensitiveness by Prolonged Heating under Water. The Bromide of Silver Sensitive to Indigo has not its Sensitiveness Changed by Heating, or, according to Mr. Farmer, only a little.*—This increase of the sensitiveness of the bromide of silver sensitive to blue by digestion or cooking has long been known, while the spectral behaviour and the characteristics described under sections 1 to 4 were first observed by me. The preparation of the highly-sensitive gelatine plates now common is based on the increase of sensitiveness effected by means of heat in

bromide of silver sensitive to blue. With increase of sensitiveness the spectral behaviour of this bromide of silver only changes from a quantitive point of view. It assumes a greener colour, and exhibits an increased sensitiveness—not only to the light blue, but also towards all the other rays of the spectrum. The other qualities—difficulty of reduction, difficult division or distribution in collodion, and indifference towards the physical developer—of bromide of silver sensitive to blue are not changed by heating. These very remarkable differences in chemical behaviour should be sufficient to establish on a firm basis the assumption that two quite distinct modifications of bromide of silver exist. H. W. Vogel, Ph.D.

—*Mittheilungen.*

A FEW HINTS ON THE EASY PREPARATION OF GELATINO-BROMIDE OR CHLORIDE PAPER.

With the ever-increasing demands exacted by photography in its various aspects, it was to be expected that something superior to the heavy, dull enlargements of the last two decades should have to come to the front and fill the demand the public have a right to make for a picture that will give a richness approaching that of silver printing but on a larger scale. The thing, however, was to find the means, and this done photographers are in a position to increase their income and do better work of the class, while amateurs are furnished with the means of getting results such as hitherto were altogether beyond their reach. These last may from small negatives revel in the production of handsome-sized pictures, wherein much of the beauty of the detail concealed in the small print is fully revealed, and effects almost unsuspected realised in the enlargements. Hours may now be by them utilised in an enjoyable way in the production of the very foundation of the large picture, namely, the preparing of the paper, which last may serve the twofold purpose of enlarging or direct printing, where rapidity of production is desirable, as is not unfrequently the case.

There is an additional charm, in the production of a developed picture, in the well-known fact that, when properly carried out, it is one of the most permanent of photographic productions; but that one must not be afraid of going to the pains of thoroughly washing, and seeing that the picture is soaked in the alumo-citric solution, is a matter that needs no comment. Cleanliness, too, in manipulation is indispensable, and each operation should be done in separate dishes, each having its own special object, and being well cleaned both before and immediately after use; otherwise stains and shortcomings are sure to result, and the process be blamed owing to the carelessness of the operator. All this I have wished to enforce on the mind at the outset, that things may be set about in the proper way, and failures avoided from the very first.

Coming to the point—namely, the production of the enamelled surface paper, for either enlarging or contact printing—I found the following to be the most direct and simplest way of setting to work:—Procure a good glass, free from flaws and scratches, or, better still, a patent plate; thoroughly clean it, and finish by polishing with French chalk. It is generally believed that the plate should be coated with collodion to obtain the high gloss. Such is not the case, however, the direct coating with emulsion producing equally good results.

The next thing then is to make a good but slow emulsion and coat direct, taking care to previously warm the glass sufficiently for the emulsion to flow over it easily, and put it down afterwards on a well-levelled surface to set. While the emulsion is setting on the plate, take a sheet of Monckhoven's enamel double transfer paper—tinted or white, at the choice of the user—or the autotype double transfer paper answers very well. Put this paper to soak in perfectly pure water; on coming out of which it must be well drained, and is then ready for application on to the emulsion film left setting. The paper is lowered gradually and carefully on the film and next lightly squeegeed, after which it is reared to dry in a cupboard *ad hoc*, and the drying should proceed with not too much heat.

After thoroughly drying, the paper is gently drawn from the glass plate, and on removal is found to have the perfect enamel gloss which conveys that depth of shadow and fulness of detail and gradation found only in albumenised prints. If proper care have been taken the papers will strip off the glass perfectly easy, without any previous coating with collodion, and, notwithstanding, with all the gloss desirable. The paper is now ready for packing or exposure, for printing by contact or for enlargement.

With regard to the emulsion proper: any of the formulæ given by the Editor in The British Journal Photographic Almanac for last year will answer, but, as it is intended to make a slow emulsion, no recourse need be had to boiling. In all probability a quarter of an hour's stewing at (say) 140° to 150° will answer every purpose. Whether there is an advantage in using the salts of potassium over those of ammonium, were better left for each one to decide for himself. What is certain is that good results are obtainable with either. It may be, too, that a less quantity of silver would answer equally well for the individual purpose in view.

I shall now enter into the manipulations gone through in enlarging, and proceed *seriatim* with details.

The first thing to do, at this stage, is to procure a perfectly flat board, place it *in situ* on a stand or easel, and on this board pin a sheet of white paper of the size of the intended enlargement, carefully focus, after which insert a diaphragm in the lens to ensure the utmost sharpness, and now cap the lens with a piece of orange glass fitted to the cap. The use of this is to admit of the picture to be still seen and enable the manipulator to adjust the sensitised paper at his ease, without injurious actinic action whatever.

As a matter of course, the length of exposure must depend, first, on the character of the light, then on the density of the negative, and finally on the speed of the emulsion proper, which, I repeat, is best slow, so as to leave plenty of latitude in exposure, the greater quantity of which is of no consequence, as what is wanted now is perfection of results, which is best attained, by amateurs at least, with ample latitude in exposure. The expert enlarger knows how to modify his developer to suit the case of slight under- or over-exposure that may occur, but it is not quite the same with one enlarging only occasionally.

The exposure made, next comes development. Since, however, so many good formulæ are already extant, I shall rest contented in saying simply that I prefer the ferrous oxalate with citric acid in minute quantity. By the way, a ten per cent. stock solution of citric acid and water is a good thing to have at hand when developing; for, if the picture come up too rapidly, at once pour off the developer in the developing cup, quickly flood the paper with plain water to arrest development in its progress, put half-a-drachm or so of the said citric acid solution in the developer, and, after stirring, now pour back the developer on the picture in progress, and things may now proceed as if a normal exposure had been given. A quick eye and hand are required for all this. With a slightly under-exposed picture more energy may properly be added to the developer. The picture developed, it should be well washed and afterwards fixed in a strong solution of hyposulphite of soda; after which wash again and put to soak for a short time in a solution of alum and citric acid, whereby greater purity of the whites is obtained and the durability of the picture increased. Finally: thoroughly wash and hang to dry. Now, if all the operations have been properly conducted, exposure correctly timed, and rational development resorted to (the negative being what it ought to be), a beautiful picture, full of delicate gradations and rich in depth, should be the result. A stout mount, perfectly smooth, is best to mount upon. Rolling completes the operations. Too much care cannot be taken in handling the paper, the face of which, I hold, should never be touched if perfection of final results be wished for.

Further Use of the Enamelled Paper.

The above are all that is requisite for a picture in black and white made from a good and suitably-retouched negative. Many, however, may wish to do something more—in fact, to tint or colour; but the gloss is then terribly repellent and obstinate, yet magnificent Vanderweyde effects are to be got with all the apparent delicate stipple. To do this the parts to be acted upon are simply abraded with finely-powdered pumice stone, applied round and round with the tip of the finger. Now that a tooth is obtained the pastels or coloured crayons are easily applied in the usual way, and exquisite vignettes are readily produced. From this it is clear that the paper is admirably fitted to take chalk. Where a highly-finished monochrome is desirable, any plain picture with a not over-dark background can be most felicitously produced by the use of the stump and chalk.

Chloride Emulsion Paper.

This form of paper produced with chloride in conjunction with citric acid, as per formula already published, is stripped from the glass as above, and may be used for printing out direct, the toning being done with gold. The advantages of this paper is the enamelled surface—which is produced as described in the course of this article—and the fine depth obtainable in the print. Once more: this surface being very fragile requires great care in handling, as the freshness once gone the charm of this sort of work is done away with immediately.

The Preparation of Plain Surfaced Paper.

There are many instances where a gloss is not only not desirable, but positively objectionable; and this is especially the case with proofs destined to pass through the artist's hand for treatment in water-colours or oil painting. He (the artist) mostly shrinks from this sort of surface, in the teeth of the public, and will audibly utter "*bonbons* box!" with a scorn unsurpassed even by Juno. Whatever may be thought of his view of the case, certain it is that frequently a need arises for absolutely plain or glossless paper. This can be produced in the following manner:—

Proper emulsion having been obtained or prepared, and sheets, large or not, of the autotype single fine transfer or well-sized paper procured, the paper is first damped thoroughly, laid on a sheet of absolutely flat glass, and its edges are turned up about a quarter of an inch all round, so as to form a kind of tray, after which the paper is perfectly smoothed flat on a glass by the aid of a damp sponge used lightly. On the paper thus prepared now pour in the centre a pool of emulsion, sufficient to cover it well all over, and make the emulsion flow from corner to corner as you would collodion, taking care to have a perfectly even coating—that is, not too thick in parts and thin in others. The drying may be done by simply leaving the paper on the glass, or, when thoroughly set, it may be hung by a pin or two or put astride on a rod to dry spontaneously. This gives a very fine paper, fit for all ordinary purposes of enlargements where a gloss is undesirable.

This paper is probably exhaustive, and meant, at anyrate, to answer any query that might be propounded in search of a reliable *modus operandi* in the individual line here treated. All available hints have been studiously dwelt upon to smooth, not only the amateur's path, but that of photographers whose experience has not lain in this direction. The system of working given is absolutely reliable, and can but tend to success where carefully and implicitly followed. At anyrate it is the result of mature experience and careful forethought, with the view of being useful to my fellow-workers, to whom I earnestly wish every success. G. H. Martyn.

MICELLANEOUS SUBJECTS.

The Illumination of the Developing Room.

To recur to the subject of the position of the lantern non-actinic screen in relation to the plate under development, it is astonishing what an advantage is gained by placing its greatest length horizontally instead of vertically. Since first pointing this out I have found the following figures bearing on the subject, though not in its application to photography, in that admirably-illustrated book, Guillemin's *Forces of Nature*:—"Of 100 rays of light received by water, glass, polished black marble, mercury, or speculum metal, with an incidence of 50 degrees, water reflects 72, glass 54, marble 60, and mercury and speculum metal 70. If the incidence augments, the number of reflected rays diminishes for the first three bodies in rapid proportion, and at most is no more than 2 or 3 at from 60 to 90 degrees, whilst under the latter incidence mercury reflects 69 rays out of 100." Therefore, supposing a photographic plate under the developer to be but three or four inches from a lantern with a window a foot high, much light from the upper part of the coloured screen finds its way to the plate, whilst more than two-thirds of that from the lower part is reflected from the surface of the liquid, and cannot touch the plate.

At present we have not nearly reached the limit at which clear, cool light can be used in a developing-room with safety; and it is to be hoped that Mr. Debenham will not stop, but push on his experiments till that limit is reached. First: the coloured screen should be a very large one—say a yard long by eighteen inches high; it should be disposed with its greatest length horizontally; and its lower edge should be at the level of the table on which the plates are developed. In no case should development begin with the plate nearer than eighteen inches from this screen; but when the image is well out, and when the bromide has well soaked the film, it may be brought nearer with impunity. Behind this screen the manipulator might have a row of gas-burners, lighting one after the other until he was able to fog a plate while developing at eighteen inches from the screen, and after first exposing the plate dry to the light for a minute, which is longer than it is likely to receive in ordinary practice. Under these conditions the brilliancy of light permissible in the developing-room will probably be most remarkable when compared with recent general experience. When plates of unusual sensitiveness are used it will only be necessary to develope them farther from the lantern. At three feet distance the power of fogging by the light will be four times less than at eighteen inches; at three yards' distance its fogging power will be thirty-six times less than at eighteen inches.

When the screen is translucent—as when tissue paper is used—the latter becomes virtually the source of the light in use. With glass, or any other medium through which the shape of the flame can be seen, there is more liability to fog. Using ground glass in the lamp is not so good as the obtaining of translucency by the opalescence of the screen; and the opalescence should not be given to glass by something which merely increases its capacity, but by surcharging it with the colouring oxide used in the manufacture. Dark greens and yellows should not be employed, but intensely bright light ones. If one plate only give the necessary opalescence more opalescence would be a disadvantage, and the plate of the second colour may be of transparent glass. There should be just enough opalescence to prevent the shape of the flame from being seen, but not a fraction more, to bring practice most into harmony with true theory. Daylight should not be used as the original source of light when uniform safety and the brightest illumination of the developing-room are desired.

Coloured oil silk will be good for those who are travelling, and should give the necessary opalescence. I am obliged to those who informed me of the silk being in the market; but Mr. Debenham's discovery will discharge all ruby colour from it in the future. With experience the size of lantern windows will largely increase; and in the future the custom will probably be to write to all the vendors of coloured oil silk for a little specimen strip only one-third of an inch wide, make a polychromatic negative of all the slips received, and then order the two which, when superimposed, give the best visual results combined with efficient absorption of the blue rays.

Should it ever be deemed necessary to add a third sheet to the lantern window, it ought to be green and not yellow, since the developer will give some of the latter colour, and it should not be the same green as the other one in the lantern. I have found that what Mr. W. Brooks says about the advantage of using the pyro. developer over and over again on different plates is quite accurate, and a very great economy.

Speculations about Cleaning Lenses.

The use of wash-leather for wiping lenses just before use has often been specially recommended in print by practical photographers; and I think that this preference is not founded merely upon fancy, but upon a scientific basis. The surface of any lens must be but ground glass; for increasing the fineness of the polish merely means increasing the fineness of the abrasion, until, in finished lenses, the irregularities of the surface are far beyond the reach of detection by the most powerful microscope.

If a thin film of grease be rubbed over common ground glass its transparency is increased; but the finer the surface of the glass the thinner must be the oily film to produce this effect, for a visible film of grease on polished glass diminishes the transparency. The law, therefore, is that the more polished the surface of the glass the thinner must be the film of grease to increase the transparency.

In the course of the manufacture of wash leather the leather is well soaked in oil, which oil is afterwards apparently removed. My idea is that actually it is not entirely removed, and that the mere trace left in the leather is just enough to give a film adapted to the increasing of the transparency of the apparently perfectly-polished surface of the lens.

German Photographers in France.

L'Anti-Prussien, a newspaper in Paris, is trying to make things "warm" for Germans residing in that city. It has just fallen foul of a photographer there in its edition of January 8th, and I translate its statements as follows:—

"On the occasion of the new year the photographers of Paris received a little rag of blue paper, in imitation of a French telegraphic form, folded up and delivered at the house. The advertisement in question came from a certain M. Fernand Brunk, 13, Rue Chaudron, Paris.

"It states, among other things—'The house of F. Brunk has no travellers or branches; it is, therefore, able to do cheaper work than all others.' Farther on is the trade-mark of an English paper-maker. The rag also says:—'Photography plays a leading part in modern art, therefore every photographer should keep in the front rank of his industry. In consequence, M. Fernand Brunk, 18, Rue Chaudron, Paris, deserves to be warmly recommended for his novel backgrounds, designed by one of the first artistic specialists on the continent, and for his other articles.'

"Finally, the tenor of this so-called telegram is as follows:—'A Happy New Year,—Fernand Brunk, 13, Chaudron, Paris.'

"Well! French photographic gentlemen! M. Fernand Brunk is nobody but the son of his father, who has an establishment at Nuremberg. If you give orders to the son in Paris at 13, rue Chaudron, the goods will come from Germany. It is unnecessary to tell you that you have good firms in Paris, French houses, jealous of their reputation, which ask nothing more than to work.

"By-the-bye, is not M. Fernand Brunk's father, perhaps, a German officer? And what grade does his son occupy in the army of our good neighbours, if we are not too inquisitive? (Signed) La Charge."

This miserable print is keeping old animosities alive by attacking various French tradesmen who employ German assistants.

Lucerne, Switzerland, January 20, 1884. W. H. Harrison.

CAMERA LUCIDA.—PALETTA OBSCURA. A STUDY IN LIGHT AND SHADOW.*

In hatching and touching your plate, which to me seems to represent the second working, think upon all the dodges of the etchers, Hayden, Hamerton, Herkomer, Whistler, &c. If you have a chemical, to eat down certain parts of it broadly, leaving the prominent parts (be sparing in prominent parts) standing out dense, do not niggle with your pencil point overmuch, except it is to blur out an accessory which may be too distinct. I do not know much about printing photographs, yet I am inclined to think it is here that the genius of the photographer may be brought out. If I were a photographer I would never leave a plate while it was printing for a second. I would try all sorts of dodges upon the sun with pieces of paper having little eccentric holes torn out where I wanted an artificial shadow to fall across my plate, by exposing the print altogether at times so as to mellow any extreme lights, painting touches of white on it to bar out the sun altogether where I wanted a mysterious gleam, whether it was on my picture or not, and never rest until I had made it my own. I may be wrong, of course, in all this; but it is the idea which now strikes me, or all that may be done already, or considered *infra dig.* or illegitimate. Yet here, I think, as in the treating of a painted picture, I imagine the photographer can liberate himself entirely from the trammels of custom, and never be at a loss for fresh tracks.

* Concluded from page 59.

In landscape photography I constantly observe good pictures rendered imperfectly through the fatal power of the camera, which must print every object before it; and yet in the printing even more than in the sorting of the plate I think much, if not all of this, might be obviated by a careful study and following up of the tricks of Rembrandt. If it be the foreground which is too plainly marked, why not take another foreground plate, and, clearing off all not required, place it over the other plate, and so let the sun strike through both and blurr that corner; or make a dark shower cloud, as in the engraving, *The Three Trees*, by covering boldly portions of the plate with paper and allow the rest to print darker, or by adroit covering and exposing simplify the whole arrangement and create divisions where you want them; a ray of light, or a part blackened, or any device that occurs to you, which is what we call "inspiration."

The magic of Rembrandt rests in this—that he seldom creates, *but he takes advantage of circumstances and local incidents* to intensify the story he is telling you. * * * * *

I take David Teniers after Rembrandt as an instance and example of successful and easy grouping. I take him as the type of a school embracing a long list of painters, ancient and modern—Wilkie, Faed, Orchardson, Cameron, Pettie, &c., &c.; and why I prefer him to our own Sir David Wilkie is not so much that Teniers was before Wilkie, because Teniers was by no means the first in that line of business, as for the reason which I think you will also agree with me if you carry back your memories to the summer exhibition, where one example of Teniers was hung in painful juxtaposition with two pictures by Wilkie belonging to Queen Victoria. If you can recal the delicate and silvery half-tones and open composition of *La Tourneuse* and compare, as no one could help doing from their close proximity, this with the hot colouring, slushy handling, and forced composition of *The Penny Wedding* and *Blind Man's Buff*, we must agree that here Teniers has the best of it. Yet I would by no means decry Sir David Wilkie, except where comparison is forced, as in this case; for I consider Sir David Wilkie, Tom Faed, and Orchardson to be the very best models a painter or a photographer can have for the composition of groups.

I am not at all prejudiced in favour of old masters or of old things, or big names, or advertised brains or dry bones; rather the reverse. I like young flesh and fresh blood, quick-beating pulses, and impetuous motions. I would rather have a living mistake than a dead perfection any day; yet, when I see the old ones far ahead of the young ones, it is both a duty and a joy to bend the knee and adore the vanished past.

Orchardson and Hugh Cameron have come up the truest to the silver and opals of Teniers, and for chaste deliberation and simplicity I can commend no one before Orchardson; he always stops painting just at the point where people should stop eating and drinking—the point this side of repletion. Study his best known examples: *Christopher Sly*, from "Taming of the Shrew," some articles of clothing and a pair of shoes in the left-hand corner, to continue the slanting line of feet of the servants waiting on Christopher; a walking-stick lying in the same line as the feet of the negro, and people behind the screen; a sheet of paper on the floor further in takes exactly the same line of direction, and the eye is no more troubled with details—we can all laugh without let. In the *Queen of Swords*, a more crowded composition, the ground lines are the same, with the Queen forming the point of the angle and a clear foreground, with the exception of a fan that carries on the same lines. In that scene from "Henry IV.," part first, *Prince Henry, Poins, and Falstaff*, we have one of the simplest, openest, and most refined specimens of humorous compositions on record. A straight, horizontal line of tapestry—broken up at the exact limit by the burly hind-part view of Sir John, the buffoonery expressed in that capacious, broad waist-belt, and the rounded folds of the doublet below it, is worthy of the mighty creator of that inflated sponge—Falstaff. A table and chair behind it keep the horizontal line, while relieving the emptiness of the floor between Falstaff and his companions. The wall starts out towards us at an angle, while, along with a chair, the Prince and Poins keep within the vanishing lines from the point of sight, which is exactly in the centre of the back view of Falstaff's waist, so that we must look (whether we like or not) first and last at him, even although, with Orchardson's usual love of refinement, he is modestly cast into half shadow.

They say Thackeray could draw a gentleman and Dickens could not. I deny this sweeping assertion in the existence of Mr. Chester of "Barnaby Rudge;" but one thing I do think, which is, that Orchardson is the painter who gives us the nearest approach to the easy insolence and *bonhomie* of a well-bred man of the world.

To return to Teniers (for a moment in passing), I cannot bring to mind one of his pictures which I have seen that could in any way be improved in the composition, added to, or taken from; every accessory tells its own portion of the general story, and this I would once more point out to the composer of a picture, along with a few simple laws which occur to me as I write. The principal object is the first object which rises up before the mind's eye, and fixes the composition when the story is heard or read, therefore the main object to be considered and first set up or drawn in—as the figure of the Queen in Orchardson's *Queen of Swords*; the philosopher nearest us in *Bacchanalian Philosophers*, by Teniers: the two front figures in Rembrandt's *Night Watch*, one dark, one light, the dark one put in by Rembrandt first; and the child with its cart even before the lighted-up woman and child who come before *The Blind Fiddler*, by Wilkie. There is too much in this composition, particularly that group of foreground objects, which bear such evident traces of having been so carefully selected and placed in such a variety of artificial carelessness—watering-pan, cabbage, box, and utensils, basin, stool, with little bat, and knife, placed so exactly, as they ought to be, like the hills of Borrowdale—all being after consideration, painty improvements, never dropped upon accidentally and not at all required. You will find nothing of this sort in Rembrandt's pictures, or in Rubens' (lavish though he is), or in Teniers', and seldom in Petty's or Orchardson's. In Vandyke's you may, or in Wilkie's, because both Vandyke and Wilkie, being Court favourites, permitted their own individuality and good taste to be oftener biassed by the buzzing of the gartered asses about them; yielding to make this or that improvement to suit a foolish patron, until their own gifts became obscured, and their taste perverted to the level of a pair of Court breeches. Rembrandt and Rubens were strong enough men always to lead the fashion, and too strong ever to be led. But the times are changed with us now, so that I do not think there is any danger of Orchardson getting spoilt by good fortune; he is not in any way hurt by it yet, at all events.

After we get the first object set up, the others all fall into place to suit that central or main object, and this rule holds with the arranging of light and shadow, as well as form;—one minute centre of light round which the half-lights range—and the deepest shadow when you can best afford it. The central form, the central light is of paramount importance—all the rest a matter of convenience, chance, and discretion.

Think less about what you may put in to help your picture as upon what you may keep out, to give it importance and repose.

Every sitter has a fine point about him, or her: find it out—the best side of the face, a nice arm, or good hand; they will reveal it to you unconsciously, before you have sighted them, and make that your first object, and all the rest subordinate so as to help that out.

Don't seize two points in one model; decide which is the most useful, and take that, without regret discarding all the others.

It may be that the only good bit is a hat, or a feather, or a pair of gloves, or a brooch. The point that first attracts your eye pleasantly is the point upon which to make your centre of vision, and around which you will arrange the rest. If it be an article of dress, of jewellery, then bring the light to bear upon it, and make all the rest in half-shades.

Study Nature for ever, if you would have any photographs you take different from the last photograph. Never take a sitter at once; leave them alone to knock about your studio while you pretend to be sorting something else, but watch them unawares; you will see a natural touch before long, a peculiar habit which they are not aware of, but by which many of their friends know them. Fix on that as your character keynote, and work up features, position, and accessories, so as not to lose sight of this peculiarity; and with this borne always in mind and a good knowledge of face and neck anatomy, without which I cannot see how anyone can touch up a negative properly, I know of no reason wherefore a photographer should not give us as complete a character study as any painter, ancient or modern, from Millais back to Albert Durer.

Yet before that state of perfection can be acquired, permit me, as one of the public and also as a frequent sufferer, to enter my protest against head-rests and long sighting, to those who still practise these abominations. No natural expression or easy posture can ever be gained, until instantaneous plates are used for everyone. Before they can well settle in their self-chosen places and posture, have them down and risk it—the chance of a spoilt picture is better than a conventional position.

Also this debasing system of smoothing away wrinkles, and blotches, and character traces. I never can see a real harsh, wrinkled face nowadays, except in some of the tintypes.

Of course I know the cry is raised that the public will have these wax productions; but as one of the public I have not yet had my own likeness taken quite right. For instance, in repose I hang my head on one side, and I have always been made to hold it straight up, like a soldier at "attention." Again, my nose is neither of a Greek or Roman caste, and yet I never do get that nose put in as I see it in a mirror, or as its humphy shadow is cast upon the wall; or, as a gentleman once closed up a wordy, if not very convincing, number of reasons against my having either the qualities to make a poet, painter, or passable labourer, by exclaiming—"Why, just look at your nose! did you ever know a clever man with a nose like that?"

I have talked a long time about realism, mixing it ever and again with the second and third objects of my lecture, as it is so impossible to separate them entirely, or to depict one properly without giving you all the rest, and therefore must now hasten to the conclusion with just a word or two about the others. Two names I may give you as specimens of feeling, M'Taggart and Hugh Cameron. I have pointed out in both what I considered to be working flaws, yet that does not prevent me from admiring their gifts and telling their virtues—rather does the one urge me to the other, as the natural promptings of manliness and fair play. Yet in neither Cameron nor M'Taggart are the qualities which render them great (to be found in engravings from their works) sufficiently strong to be utilised in the photographic studio.

For feeling and sentiment I would point out Robert Macgregor amongst our Scottish artists; through using low tones he is a very useful study for a photographer. We want yet to see general, low, and soft tones about our photographs, as well as strong and rugged effects softened down.

I could mention many others, but when I come to examine their work I find so many evidences of the palette obscuring only what the camera has made a little too lucid, my conscience bids me pause. I would like to say that they had feeling, but I see more of flimsy affectation and shallow make-believe woolliness instead of soul-stirring passion. Yet "John Blair" has feeling and tenderness, Robert Herdman has sentiment, Lockhart has force, Herkomer has force, feeling, sentiment and passion, and so many more that I cannot mention, unhonoured, and some honoured in whose works I can trace nothing original at all.

In France there is a school rising, who with the brush are trying to compete with the camera. *The Impressionists*, along with the camera, are yet fated to produce a great revolution in art. They aim at giving the impression, effect, or sensation of an instantaneous action or emotion or phase; not the phase exactly, but the swift impression which it leaves upon the mind of the spectator, with form, as it were—that is, with paints and brushes striving to embody the soul of Nature, and when the two are joined, the result will be—*perfection*.

To finish by bringing up the name which I have hitherto kept back, the exception, about which some time ago I promised to tell you—the sweetest, tenderest, mightiest art soul that ever was chained inside of a mortal body, and prompted the fingers to move as it wanted; the purest, saddest mind that ever writhed neglected and found its reward so late; the soul now free and stirring up a crowd with its pathetic activity, to be like it, pure and true—I mean *Jean-François Millet*, the French peasant painter. Mr. Hunt says of him—"For years Millet painted beautiful things, and nobody looked at them. They fascinated me, and I would go to Barbison and spend all the money I could get in buying his pictures. I brought them to Boston. '*What is that horrid thing?*' '*Oh! it's a sketch by a friend of mine.*' Now he is the greatest painter in Europe."

That is a painter's verdict about a painter.

One of his pictures is vivid in my mind just now. There is a print of it in that wonderful illustrated magazine, *Scribner's Monthly*, where engravings look like paintings or idealised photographs.

It is called *The Sower*—the dim figure of a labourer scattering seed over a ploughed field with one hand, and holding his apron filled with embryo life in the other. In the distance, and lighted up by the sun, a team of bullocks are dragging the plough, and a flight of birds over beyond the seed. That is the whole composition put into bald words. But as it has been rendered by this painter it has an embodiment of all which I have tried to explain—the spirit and body of living, working, suffering nature.

What would I not give (if I had it) to see a photograph done like that! And it can be done if you labour enough, know enough, and feel enough.

As I look upon *The Sower*, I am drawn into it, mesmerised and rendered clairvoyant; I am *en rapport* with the freed spirit which has left, along with the delicate aroma of its departing wings, a portion of its own personality, its own immortality—vague and tender—greater than Raphael, or Rembrandt, or Albert Durer; for it has taken the deepest root within humanity.

Tenderly I look upon it, not too boldly, for it seems vibrating with a sensuous existence; it clutches at my heart-sinews as it reveals the parables of Christ, accompanied by sobbing notes of melancholy spirit-music—the far-off strikings of angel harp-strings, indefinite but ravishing.

And the painter's body lies under the earth—that St. John face, with its misty development of hair; the maddened stag driven by the hunters and the hounds over the garden fence, into the snow-covered garden on that January morning of 1875,* past the dying man's window, and ruthlessly slaughtered under the eyes of the dying man; yielding up its noble life for a bit of sport, the hot-red blood sinking through the cold, white snow, and soaking into the covered hearts of the green plants beneath. One up-turned glance of the glazing eyes met the down-turned glance of the glazing eyes, and so—filled with despair and pity—two souls—the soul of a stag and the soul of a painter—drifted out into the morning light. HUME NISBET.

DEVELOPING DISHES. By F. W. HART, Kingsland-green, N.

WE have received from Mr. F. W. Hart a specimen of a new developing dish which he has just introduced. This is constructed of celluloid—a material which lends itself admirably to this and similar purposes, being lighter, less brittle, and cheaper than ebonite, and, at the same time, equally serviceable. The new dishes are elegant in appearance, and are provided with light ribs at the bottom to prevent the adhesion of the plate. The colour is white, or nearly so, which may prove an objection to some who have accustomed themselves to ebonite; but this is a fault which may be easily remedied.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Society, held on Thursday, the 24th instant, Mr. W. Coles occupied the chair.

MR. A. COWAN said that he had recently fitted his dark room with the green glass and yellow paper proposed by Mr. Debenham, and at the same time had arranged to let reflected light only fall upon the glass, as recommended by Mr. Starnes. The advantage of using reflected light, he thought, was that the window was equally lighted all over instead of being brightly lighted at the place immediately in front of the gas jet which served as the source of light. His light was glazed with a square of the green glass 24 × 18 inches, supplemented by four thicknesses of the yellow paper. Behind this was a gas flame with a tin screen of just sufficient size to prevent the light from the flame impinging on the window. Behind the flame was a reflecting surface of the same yellow paper arranged in a concave form. He found that he had more light to work by than he formerly had when employing the usual red mediums, and to test its safety he had exposed three portions of a plate for periods of five, ten, and fifteen minutes—the remaining portion being kept covered—within a few inches of the window. This plate was handed round, but no trace of an image could be seen on any part of it. The plate was a rapid one, by one of the best known commercial manufacturers. With his former dark-room light he could get a distinct impression on the plate in five seconds, and a strong one in fifteen seconds. An example of this he had shown at a previous meeting.

MR. W. M. ASHMAN stated that for travelling purposes he thought the use of a spirit lamp with salt in the wick very convenient, as the materials could be obtained everywhere. He had been trying the photographic power of the flame by exposing plates to its light for periods of five minutes. At a distance of twelve inches from the uncovered flame a distinct image was obtained. With a sheet of ground glass six inches from the flame, and the plate twelve inches from the glass, there was still an image. Substituting opal glass for the ground glass the image was very faint. He (Mr. Ashman) also showed the results of some experiments made with a small oil lantern and various mediums. Two thicknesses of ruby glass had, with five minutes' exposure at twelve inches' distance, given a transparency. One thickness of ground glass and one thickness of orange glass had also sufficed to give an image; but one thickness of ruby glass and one of oiled orange paper seemed to be safe.

Mr. J. B. B. Wellington showed some transparencies for the lantern, made upon bromide plates and developed with iron, closely resembling the cooler of the tones obtained upon chloride plates. The emulsion was prepared as follows:—

Nitrate of silver	50 grains.
Heinrich's gelatine	20 ,,
Water	5 ounces.

The nitrate of silver is first converted into citrate by citrate of ammonia, and then redissolved in ammonia—

Bromide of potassium	40 grains.
Heinrich's gelatine	20 ,,
Water	5 ounces.

The two solutions were mixed at a temperature of 150°. Two hundred grains of the same gelatine were then added and stirred till dissolved. When cold it was washed in the usual way. The development was conducted with ferrous oxalate solution, to which had been added from twenty to eighty grains of bromide of potassium to the ounce. The more bromide added the warmer was the resulting tone. The exposure had been from half-a-minute to two minutes at a distance of six inches from a fish-tail burner.

Mr. Garrett showed a beautiful transparency obtained on a commercial chloride plate. The exposure had been six seconds to diffused daylight at four o'clock, and with the developer marked as No. 2 on Mr. Cowan's paper.

Mr. Ashman said that when describing his first experiments with Mr. Newton's developer he had said that there was not much gain from the addition of iodide of mercury. Fresh experiments had convinced him that there was no gain at all, and he should not advise anyone to waste time over the process.

Mr. Cowan had made experiments with the plan, and now showed the results, from which he concluded that iodide of mercury was not an accelerator, that there was no advantage in its employment, and none from the use of soda water instead of ammonia in the developer.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The first "popular evening" took place in Queen-street Hall, on Wednesday evening, the 23rd inst.

The exhibition consisted of about 150 pictures, selected from the works produced by the members during the past year. Many were of a high order of merit, and the very large audience frequently showed its appreciation by applauding the views, which were exhibited by the aid of Mr. M'Kean's carrier.

The contributors were Messrs. R. Murray, C.E., Wm. Mitchell, F. Brigmen, A. Matheson, R. Irving, Jas. Crighton, Wm. Neilson, M. Wane, Fraser, Notman, A. B. Stewart, F. Moffat, W. T. Bashford, Crooke, Macdonald, M'Kean, M. Scott, H. Watson, and S. Tamkin.

The transparencies were produced by "coffee" plates, collodio-chloride, gelatino-chloride, bromide, and by the wet process, and most pleasing effects were also produced by different toning agents. Messrs. Turnbull and M'Kean manipulated the lantern, and Mr. Bashford occupied the platform.

PHOTOGRAPHIC SOCIETY OF VIENNA.

The last meeting in 1883 of this Society took place on the 11th December, when the chair was taken by Dr. Hornig. A number of new members were admitted.

The Chairman announced the death of Herr Jagemann, one of the oldest members of the Society. He also read a communication from Dr. Stolze, in the name of the Berlin Photographic Society, inviting the co-operation of the Photographic Society of Vienna in the projected photographic exhibition at Berlin in 1884. The matter was remitted to the committee of management for consideration.

A communication from Herr Obernetter respecting his photo-engraving process was then read.

Major Volkmer presented a report of the work done during the year at the Imperial Royal Military Geographic Institute, of which he is the director.

Herr Berger said that the arctic views he lately showed were but a small part of the series taken by Marine Lieutenant Basso on the island of Jan Mayen, when he accompanied Graf Wilczek's polar expedition. Most of the negatives were developed on the spot where they were taken, only a few being brought to Vienna for Herr Berger to develope.

Part of Professor Vogel's collection of North American photographs were next shown, and were followed by a series of portraits taken by electric light by Herr Lewitsky, of St. Petersburg.

Professor Eder then made some remarks respecting a number of miscellaneous matters, having a bearing upon different departments of photography, such as the density of solutions of potassic oxalate; the employment of hemp for the filtration of emulsion; the sensitiveness to light of a mixture of gelatine and red prussiate of potash; on the employment of salts of uranium in gelatine emulsion; the action of pre-lighting upon gelatino-bromide of silver, and the action of heat upon gelatine plates.

Owing to the lateness of the hour some of the business placed on the order of the day had to be deferred to the first meeting in the new year, and the meeting was adjourned.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

This Association met, for the first time this year, on Friday, the 4th ult., when the chair was occupied by Professor H. W. Vogel, the President.

The Chairman showed a cabinet-sized landscape in which several flashes of light were photographed. Herr Hänsel, in a letter which accompanied the picture, said that he noticed a storm coming on, so he placed a gelatine plate in the dark slide, and, having placed the latter in the camera, directed the uncovered lens towards the landscape, leaving it uncovered all night, so that the flashes which came across the field of the picture recorded themselves photographically. The plate being exposed during the night there were but slight traces of the landscape. The flashes as represented in the photograph did not at all correspond with the preconceived ideas of the zigzag course of lightning.

One provincial member requested some information respecting Dallmeyer lenses; another asked for advice respecting the choice of a method of enlarging.

Herr Quidde recommended the use of Lamy's paper, which permits of printing by lamp light. Herren Graf and Joop had never been able to get such good results with this process as Herr Talbot, and, besides, many people objected to the cold grey tone of the pictures.

Herr Joop thought the best results were to be got by enlarged plates; that is, by making a transparency, and then making an enlarged negative from that.

Herr Quidde then spoke of Herr Halwas's method of enlarging on canvas in order to paint upon, and inquired whether the film of emulsion did not prevent the oil colours from adhering to the linen.

Herr Joop had not found this to be the case. He was in the habit of washing over the surface of the prepared canvas with soda, and then with citric acid. This rendered it matt, and so assisted the emulsion and oil colour to adhere.

Herr Hase inquired for a cure for the albumenised paper repelling the silver bath or taking it on in streaks.

Herr Graf had often remarked that fault in new paper, seldom in old, and he prevented it by rubbing the paper with cotton wool before silvering.

Herr Haberlandt found, now that paper is not so much salted as it used to be, that this fault was apt to occur whenever the silver bath was too strong.

The Chairman called attention to two articles in the *Photographische Correspondenz*, in which the subject of patenting inventions is placed in a true light. It was remarked that a process was by no means necessarily to be considered old because the operations of which it consisted were already known; the novelty might lie in the combination. He (the Chairman) showed some American plaques, read a communication from Herr Obernetter describing his photo-engraving process, and finally showed a collection of views in the Nile valley taken by Wilson, of Philadelphia.

Herr Graf compared them with his recollections of the Egyptian views shown at the Berlin Exhibition of 1865, by Bedford. Bedford's views were taken upon wet plates and Wilson's upon dry plates. Wilson's plates were not developed until seven months after they were exposed. He thought Bedford had selected the most artistic points of view, while Wilson's were selected more with a view to being instructive and illustrating the geography of the country.

The meeting was shortly afterwards adjourned.

Correspondence.

THE LANTERN IN THE UNITED STATES.

To the Editors.

Gentlemen,—I observe that in his paper at the opening meeting of this session of the South London Photographic Society, Mr. J. T. Taylor spoke of the United States of America as a good field in which to work the optical lantern from the commercial point of view. Would it be asking that gentleman too much to give some particulars concerning the state of this business in the New World, both as regards lanterns and slides, and to say where in his estimation a business of this nature might best be established with a view to its eventually becoming largely developed?

I have seen several American lanterns, including the Marcy sciopticon, and the lime light exhibition of Mr. Muybridge by one of a better class, but I did not think that these represented the highest capabilities of the lantern.

I would also feel obliged if an indication of the prices of lanterns and slides could be given.—I am, yours, &c., T. P. Hicks.

London, January 28, 1884.

[Perhaps Mr. Taylor will kindly respond.—Eds.]

"DIFFUSED LIGHT FOR THE DARK ROOM."

To the Editors.

Gentlemen,—I see a letter in one of your scientific contemporaries on the popular topic of dark-room illumination, in which the experimentalist seems to have tried his new light in an ingenious but not very convincing manner.

After exposing the half-covered plates to the light under trial he appears *to have fixed them without development;* then he exultingly writes that "each plate showed clear glass."

Would this scientist be surprised to find that if he had exposed these plates in a similar way to the unobscured midday sun he would have got the same result?—I am, yours, &c., K. Alnwyke Browne.

January 29, 1884.

SENSITOMETERS.

To the Editors.

Gentlemen,—Having just read Mr. W. K. Burton's able remarks upon the above on page 39 in your issue of January 18th, permit me to say that I entirely agree with them, and therefore accord him my best thanks. But at the same time I would refer him to my paper as printed in the Parent Society's *Journal*, page 163, line 6, wherein I define sensitiveness to be the time necessary to produce the minimum of effect upon a film; consequently my remarks were in reference to the production of the minimum tint in both cases when the films were of uniform composition, the light employed being the variable condition.

On page 164 I mention that I intend to continue the subject, and I hope before long, with the co-operation of a friend, to bring the subject before the Society, when we shall describe a method of standardising any tint, for the twofold purpose—Firstly, to estimate the general sensitiveness, *i.e.*, the time necessary to register a series of tints; and, secondly, whether, and in what direction, their relative gradation will be disturbed by the process of registration.—I am, yours, &c., JAMES B. SPURGE.

January 29, 1884.

DEVELOPING.

To the EDITORS.

GENTLEMEN,—As one who values the utterances of Mr. B. J. Edwards because of their general soundness and practical value, please allow me to ask him to publically detail the disadvantages he states in the ALMANAC that he has found in the sulphite of soda developer after trying it in every shape and form.

I have been trying the plates of various English makers, and find a general excellence as regards cleanliness and freedom from fog, but much variety in their powers of giving true gradation, rich and varied. General attention should be concentrated on their differences in point of gradation, with which I find more rests with the plate itself than with the developer.—I am, yours, &c., QUESTIONER.

PHOTOGRAPHIC EXHIBITIONS.

To the EDITORS.

GENTLEMEN,—Lor! what a funny man Mr. Browne is, to be sure! And I am certain it is my letter in the Journal of the 18th instant that is being honoured with his notice, because there is no other communication anent photographic exhibitions inserted for that week.

Of course, K. Alnwyke writes as though I had expressed myself quite *tout au contraire* to what I really do; but that's nothing. We all know that the excellent "science" of wrangling would almost cease to exist but for the disputants' wilful misinterpretation of each other. Besides, if K. Alnwyke had only recognised what I *did* write, why then he would have had nothing to reply about, and all that keenly pungent satire of his would have been lost to the readers of the Journal.

As I am writing, kindly let me supplement my last communication with the relation of another incident which came immediately under my notice at an exhibition (say) within 500 miles of Newcastle. You see, gentlemen, I must be cautious while K. Alnwyke and his ready pen are about.

A. and B. spend some time together in a picturesque neighbourhood adjacent to the town of this exhibition, and they jointly secure a series of photographic pictures of more or less merit. A. developes the negatives, and sends prints from them to this exhibition, with his name appended. B. acts as one of the judges who dispense the medals here, and A.'s case of exhibits are medalled! I may add that I believe B. only knows of being judge after the pictures are taken.

Naturally the virtuous indignation of you and me and K. Alnwyke would be at once roused if any doubt were expressed as to the fairness of this transaction. Somehow, though, there always are people mean enough to question these little coincidences; but judges have "an invidious, a laborious, a difficult, and an utterly thankless task," even as have the hanging committees, and, therefore, what mere exhibitor shall dare to complain even if judges award medals to the panels of the exhibition doors, or the committee hang the pictures upside down? Let such ungrateful malcontents dread the vengeance of K. Alnwyke and myself.—I am, yours, &c., LYDDELL SAWYER.

24, *Upper Bedford-street, W.C., January* 29, 1884.

Notes and Queries.

A PHOTOGRAPHER is ordered to take a group of an athletic club, and exposes a print in his show-case. He is written to by one of the group, in a very high style, threatening "proceedings" unless it is removed. With your varied experiences you might advise.—PUBLISHER.

I. K. T. inquires:—"Could you kindly recommend me some one who builds small studios and sends them to order (as greenhouses are sent), and has a knowledge of what is wanted?"——In reply: Although we are not aware of any, some reader may be able to give a response.

Is there any method by which I can blacken brass mountings of lenses that have been soldered with common tin solder? I am aware of the method of obtaining a black stain both by nitrate of copper and also by chloride of platinum; but the former necessitates the employment of a degree of heat that would undo the soldering, while the stain produced by the latter is bad for my requirements. Any information will be thankfully received.—E. T. H.

I SHALL feel greatly obliged if you, or some of your numerous correspondents, can assist me out of a difficulty. My studio is built in a garden, for which I pay an annual ground rent. The building, however, is my own, being erected nearly twenty years since. I have been all that time using the north light, and that is the only point free from obstruction to the studio. My neighbour is now preparing to build and obstruct that light. I shall be glad to know what is the law in such a case, and also which would be the best way to oppose.—PERPLEXED.

WILL you please tell me how I can remove collodion from a gelatine negative that has been so coated instead of varnish?—ALFRED JOHNSON.

1. WOULD a Dallmeyer's rapid rectilinear lens (diameter 1¼ inch, focus 7½ inches) enlarge direct, from cabinet and *carte-de-visite* negatives, all sizes up to 24 × 20?—2. Would it do as well as an ordinary Dallmeyer's *carte* lens, and which would take the longer exposure?—3. Would the rectilinear require more room between the negative and a 24 × 20 enlargement than the *carte* lens? I am "going in" for taking views, groups, &c., and enlarging them, and should be glad if the same lens would do for both.—LENS.——In reply: 1. Yes.—2. The *carte* lens will be the more rapid.—3. See the table for enlargements in our ALMANAC. From that you may obtain all the measurements necessary.

J. H. B. says:—I have a whole-plate lens which is wrong in the chemical focus; that is, when the picture is focussed sharp on the ground glass, on development it is not sharp. It is not the camera which is at fault; it is the lens. Can it be corrected? and how?——In reply: Let "J. H. B." ascertain, first of all, whether the lens is over-corrected or under-corrected for colour. Then, assuming that the front lens is the defaulter let him separate its component parts and regrind the contact surfaces, or send them to be reground. If over-correction be the fault indicated by his examination, let a longer radius of curvature be selected; but in the event of under-correction the radius must be shorter.

IN reply to a question put by "Broken Frame" relative to the right of photographers to exhibit specimens and to recover damages from anyone who smashes the frame in which such exhibit is made, I would suggest the desirableness of photographers joining together to have the opinion of some eminent counsel, and thus have the question definitely settled.—D. JONES.

I HAVE heard of several brother photographers who have "got to loggerheads" with their clients for placing their "counterfeit presentments" in show-cases, and some have had their frames broken. On mentioning this subject to a legal friend, he said that the breaking of the frame by any aggrieved party could not be upheld in law, and any photographer whose property was thus treated might sue for, and obtain, damages. "Broken Frame" will thus be enabled to obtain redress.—B. E. W.

IF Dr. Browne will substitute chloride of platinum for chloride of gold in the toning bath, making it a little stronger, he will get the platinotype tone desired. Were it not that a small modicum of silver is still left in the platinum-toned print there would be but little, if any, difference between the print thus toned and a platinotype print by the Willis process. Perhaps, however, I ought not to write thus dogmatically, but rather cast my statement in the form of a query, thus: Would there be any difference between them?—G. T. L.

THE question raised by "Broken Frame," involving the right of photographers to exhibit specimens, is one of great interest to the profession, and I hope it will be well ventilated. I give the following as a contribution towards its elucidation:—Several years ago a photographer, of Bold-street, Liverpool, summoned a timber merchant of that city for £1 19s. 6d. for damage alleged to have been wilfully done to a show-case. It appears that a photograph of a lady had been exhibited contrary to the desires of her friends, by whom its removal was requested. This not having been complied with, after the lapse of a few days the defendant pushed his umbrella through the glass and destroyed the specimen. The judge said that, however annoying it might be to ladies to have their portraits thus publicly exhibited against their wish, the act of destruction could not be justified, and the plaintiff obtained a verdict for 10s., being the amount at which the defendant himself estimated the damage done. Still, as a matter of expediency and altogether apart from the legal rights or wrongs of the case, I hold that any photographer who desires to stand well with the public should respond *immediately* to any request to suppress the exhibition of a specimen.—W. BLACKIE.

Exchange Column.

No charge is made for inserting these announcements; but in no case do we insert any article merely OFFERED FOR SALE, *that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a* NOM DE PLUME *be thought desirable), otherwise the notice will not appear.*

I will exchange an "eclipse" light for anything useful.—Address, J. HEMOTT, Photographer, Berwick.

Seavey's "Sarah Bernhardt" interior, as good as new, 8 × 7, in exchange for another interior in same condition.—Address, D. BORDLEY, Newport-road, Stafford.

I will exchange Seavey's stilo and gate for Moulton's washer or No. 4 Ross' portable symmetrical, or offers.—Address, F. M. SUTCLIFFE, Whitby, Yorks.

I will exchange two editions of *Cassell's Natural History* (one volume bound), in perfect condition, for camera, or tripod, or anything useful in photography.—Address, E. B., 10, Wellington-street, Gloucester.

I will exchange Entrekin cabinet burnisher with Bunsen burner, new condition, or a whole portrait and view lens, by Hermagis, for a small dry-plate apparatus.—Address, JOSEPH ROSS, Cadlaverock, Dumfriesshire, N.B.

Wanted 5 × 4 medium angle doublet rotating stops and sky-shade, or 5 × 4 rapid symmetrical, in exchange for 12 × 10 mahogany double dark slide and folding retouching desk (outside measure 20 × 16), with little cash; offers solicited.—Address, C. COLEBURN, The Pottery, Green-lane, Finsbury Park, N.

I will exchange Dallmeyer's *carte* lens, 12 × 10 and 10 × 8 camera; also 12 × 10 rolling-press, in exchange for studio furniture, or anything useful. —Address, PHOTOGRAPHIC Co., 26, Congreve-street, Birmingham.

I will exchange a Carver's patent bicycle, 53-inch, all bright, and all the latest improvements, cost £13, for a good whole-plate tourist camera and Ross' rapid symmetrical lens.—Address, R. S. BONNALLO, 18, Church-drive, Carrington, Notts.

Wanted, a good tourist camera, for $7\frac{1}{2} \times 5$ plates, with three double backs, and swing-back action, in exchange for a three-lens gem camera with dark slide, or whole cash; will give in part exchange.—Address, A. C. HILLIER, 1, Victoria-terrace, Snow-hill, Bath.

I will exchange THE BRITISH JOURNAL OF PHOTOGRAPHY for 1883 (quite clean), and BRITISH JOURNAL ALMANAC, and the *Year Book of Photography*, for anything useful in photography.—Address, JAMES HENWOOD, 79, Ashford-road, Eastbourne, Sussex.

I will exchange a first-class rolling-press, with steel plate 18 × 12 (cost £9), in excellent condition, or a capital Victoria or *carte mignonne* camera with four lenses (nearly new), to take eight pictures on a plate $7 \times 4\frac{1}{2}$, for a Ross' portable symmetrical No. 3 or 4.—Address, PHOTOGRAPHER, Cambray studio, Cheltenham.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

PHOTOGRAPHS REGISTERED—

Richard George Arnold, Stafford-street, Market Drayton.—*Two Photographs of St. Mary's Church, Market Drayton.*

Thomas Forrest, Cambrian Studio, 14, Market-street, Pontypridd.—*Photograph of Dr. William Price, Druidic Bard.*

A. S. HOPKINS.—Any London dealer in bookbinders' materials will supply the kind of leather you require. We cannot undertake to furnish addresses in this column.

C. A. S.—The enamels have undoubtedly been over-fired, hence the cause of their faint, sunken-in appearance. Try again with far less heat, even at the risk of underdoing it. They can be returned to the muffle for more heat, if required.

J. BERRYMAN.—We regret that after examining the enamel we threw it aside, and cannot now lay our hands upon it. However, we will make further search, and, if found, send it back. It is a pity you did not say you wished it to be returned.

CHAS. WILSON (Leeds).—You may safely tone the albumen pictures in the bath as described in the article, provided the pictures are thoroughly washed afterwards. Take care that the quantity of gold is kept up, otherwise you will be toning with sulphur.

S. A. BIGGS.—If you wish to preserve the fullest gloss on the prints you must cement the mounts to them while they are still on the glass. If they are removed first there is no mountant that can be employed which will not, in a measure, destroy the highly-glazed surface.

R. C. MICHELL.—On the whole you cannot do better than make choice of the lantern with the four and a-half inch condensers. The smaller, for some purposes, might answer best; but, as you say, you will occasionally require it for enlarging purposes, select the larger of the two instruments without hesitation.

COPPER.—Tinfoil may be precured from any operative chemist, and of different thicknesses. For your purpose you require the thinnest you can procure. Mind that the surface must be thoroughly cleansed with a solution of potash, otherwise you will experience a difficulty in getting upon it an even deposit of copper.

A. P. WILLIAMS.—The "tunnel" form of studio is not much in favour at the present day. It was much lauded some years back; but many who constructed studios on that principle quickly altered them to the old ridge roof or "lean-to" form. However, good work has been done in such studios, and some prefer them still above all others.

COLLIN.—The gelatino-bromide prints are all very much under-exposed and over-developed. We can quite understand that the development occupied a long time to get out such details as you have obtained. The fault is not in the process, but in your want of judgment in the exposure. When you make another essay, try giving at least double the exposure.

B. A. (Cambs.).—The relief not being sufficiently high may arise from several causes. If too much pigment be added to the gelatine the light cannot penetrate deeply into the film, so that there will, of necessity, be very little relief. If the negative be too thin it will be impossible to obtain high relief. Under-printing is also a fertile source of want of relief.

R. HIGGS.—The specimen forwarded is an excellent sample of photography of a very unfavourable subject as a sitter. The poor fellow appears to be nearly strangled by his shirt collar, while the "horsey" pin appears to have been fixed too tightly. We fancy the general "get up" of the sitter is the chief fault with the portrait. Pay no attention to such criticism.

ARTEMUS.—We cannot in this column undertake to give you practical instructions in the preparation of enamelled paper for collotype printing. Even if we could you would find it more much advantageous to purchase it ready prepared than to attempt to prepare it for yourself. Messrs. Spicer Brothers, Bridge-street, Blackfriars, E.C., will, no doubt, let you have a few sheets for experimental purposes.

INQUIRER.—Several articles on the subject appeared in our last volume, to which we refer you.

U. V. W.—If the examples forwarded are fair specimens of your general work we should certainly not advise you to proceed to New Zealand with the idea of meeting with an appointment as operator in any first-class establishment. Our advice is—make yourself much more proficient than you now are before starting. Bear in mind that there are quite as good and artistic photographers in the colonies as there are in England, and equally good work is expected from operators.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 6th inst., the subject for discussion will be—*On Portable Cameras.*

EXTENSIVE POSTOFFICE ROBBERIES.—At the Central Criminal Court, on Monday last, John Griffiths, 38, photographer, pleaded guilty to stealing a large number of cheques from letters which he had stolen from private letter-boxes, and to forging the endorsements to the cheques. The Recorder sentenced him to ten years' penal servitude.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—The next ordinary monthly meeting of this Society will be held at the house of the Society of Arts, John-street, Adelphi, on Thursday evening next, the 7th inst., at eight o'clock, when the subject will be—*Willesden Paper and Canvas, and Some of their Uses in Connection with Photography.* The following, from the question-box, will be discussed:—*Are Pictures upon Ready-Sensitised Paper likely to be More or Less Permanent than those upon Paper Freshly Prepared?*

THE ORIGINAL AND THE PICTURE.—Last week, at Stockton County Court, Mary Ann Best, wife of Edward Best, blacksmith, South Stockton, sued William Baker, photographer, for two guineas, being the amount paid to defendant for a painted portrait of plaintiff. Seven shillings had been paid into court, and plaintiff had received one dozen *cartes-de-visite*, value ten shillings. Miss Baker appeared for defendant. The portrait was exhibited in court, and its striking contrast to plaintiff created considerable amusement.—Miss Baker said the portrait had been executed three years since, and was exactly like what plaintiff then was.—His Honour pointed out a distortion in one of the eyes, and an entire absence of colour in the portrait, plaintiff being a handsome, buxom, fresh-coloured lady.—Miss Baker remarked, amidst much laughter, that women change a very great deal in the space of three years.—A verdict was given for plaintiff, the price of the *cartes* received being deducted.

BLACK PATCH *versus* CARBON TRANSFERS.—The last new Parisian agony, as exhibited in the Boulevard St. Michel, goes a step beyond the carbon process in its use of a flexible support. The picture is not transferred to paper, but to the human skin! A young *fiancée* who is separated by a cruel fate from her beloved object no longer carries about his portrait in a brooch or locket, but goes to the photographer's and has it printed upon the skin of her own fair arm! Among savage races tatooing is gradually giving way before the march of civilisation, and a blue anchor on the arm is no longer one of the indispensable ornaments of the "British tar." It is, therefore, amusing to find it reviving in the very centre of civilisation. There is also a rumour current that the black court plaster patches on the face, as worn in the early days of hoops and powder, are to be revived next season. Will some enterprising photographer get up more elaborate designs than the court plaster cut with scissors could provide, and offer them to his fair *clientèle*? A coach and four worn across the forehead was a masterpiece; but that is nothing to what could now be done with judiciously-arranged carbon transfers.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician,
For the Week ending January 30, 1884.
THESE OBSERVATIONS ARE TAKEN AT 8.30 A.M.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1240. Vol. XXXI.—FEBRUARY 8, 1884.

THE TREATMENT OF NEGATIVES AFTER DEVELOPMENT.

We have lately been experimenting upon variations of the usual routine through which a negative passes after it is fully developed, with the idea of adding to their certainty and efficiency, and the results we have obtained have been sufficiently encouraging to warrant our giving some details of the methods we followed. At first sight the matter seems simple enough; but careful workers will bear us out in our assertion that many conditions leading to irregularity of one kind or another are readily manifested at this stage of the process. The usual plan of treatment after development is to wash the plate more or less completely (generally less) and then to fix and again wash—a mode varied, more especially in hot weather, by immersion in the alum bath, followed by washing before fixing.

The first point we would touch upon is the washing after developing. It is usually understood to be an advantage to wash the negative well, and many (perhaps most) photographers do so wash, performing the operation in many ways—placing it either in running water under a tap or in a dish to soak. It will always be noticed that unless the negative be almost violently washed under a tap a certain access of density will occur before fixing, so that the ultimate density may be greater or less than expected according to the mode of washing or the length of time it occupies. We believe that a majority of operators employ the alum bath before fixing—not as an absolute necessity, but as a safeguard against possible frilling—and our remarks will be mainly founded upon that method.

If the washing be not performed well before "aluming," there is danger that the ammonia may precipitate alumina within the texture of the film, and so cause the negative, after drying, to be slightly opalescent, thus injuring its printing qualities. It is, however, doubtful whether this is not prevented by the gelatine film, many similar organic substances preventing such precipitation. Granting, however, for the sake of cleanliness of solutions alone, that the negative is freed from the major portion of the "pyro.," it will be found, if the alum solution be much used, that it will intensify the tendency of the plate to discolour, in consequence of the pyro. not being at first entirely removed—a state of things to be avoided as much as possible if the "wet plate character" is to be attained. In fact, it may be said that all delay prior to fixing tends to produce the pyro. stain to a certain extent.

Keeping this fact in view, it occurred to us that if the alum were to be slightly acidified there would be a distinct gain up to that point in the proceedings; for a washing almost perfunctory in character might be given before placing the negative in the solution, as the acid it contained would perform the double function of assisting to remove any already existent discolouration, and neutralising any ammonia the plate so slightly washed might bring with it. There would thus be no possible danger of the alum being decomposed by ammonia, and, what is even more important, there would be no chance of any increment of intensity while the plate was in the alum, as an alkali is needed to induce the development. Staining would also be prevented, as it is known that the discolouration of pyro. solutions is a function of their alkalinity.

The danger entailed by the adoption of the plan now suggested would be the decomposition of the hypo. bath by the premature placing therein of the plate before it was quite freed of the acid solutions. The additional risk to the negative, however, is less than might be supposed; for, if there were acid in the film, so also would there be alum, and the decomposition that occurs when hypo. and alum are mixed together is well known, and is not less likely to be injurious to the image than the change brought about by mixing dilute acid with the hypo. The effect of the decomposition of the hypo. must be looked at in two lights:—First, the probability of compounds being produced that would by their continued presence lead to the ultimate fading of the image; and, secondly, the production within the film of some insoluble matter that could not be removed by washing, and would interfere with its perfect printing qualities.

We look upon the former as a contingency far from probable, while the latter would be a more serious evil, as its being brought about within the substance of the film would prevent its removal by washing, no matter to what extent carried out. There is a great deal said and written about the production of acid, sulphurous, and other compounds, most of which are soluble, while sulphide of silver, insoluble, meets with less notice. A negative subjected to the action of decomposing hypo. lies in quite a different category from that in which an albumenised paper print would be placed, and the results of decomposing hypo. upon each would be quite different. By these remarks we must not be supposed to be endeavouring to convey the notion that we consider the decomposition of the hypo. a matter of no consequence. Far from it: we would avoid it in every way; but if it must be looked in the face let it be fairly done.

If the plan of acidifying the alum solution be adopted it will, therefore, be desirable to wash as well as possible to remove all traces of acid and alum, and thus prevent any doubt being cast upon the permanence of the negatives. We would say that all through, while writing in this connection of "alum," we refer to chrome alum. A small quantity going far, half-an-ounce of this alum to a quart of water will form a solution sufficiently strong for all practical purposes, and if a drachm of citric acid be added to this quantity a solution such as we have been experimenting with will be made. We choose citric in preference to other acids as being another safeguard against the precipitation of alumina, the presence of soluble citrates preventing such precipitation.

We have found that the colour and general appearance of the negative are most decidedly improved by this slight innovation; in fact, so much is this the case that the plan may be found worthy of adoption on this very account alone, even by those who work a plate not requiring the use of alum. It may be adopted in lieu of the preliminary wash that would be given when the alum was not employed, and would not entail the expenditure of any more time, while the colour of the negative would be wonderfully improved.

Finally: we may say that where any lingering doubt exists as to the possibility of danger through the introduction into the hypo. of plates imperfectly freed from acid, all chance of it would be removed by making the hypo. solutions slightly alkaline with ammonia. The decolorising effects of the acid would have been called into play, and, even with only a slight washing before immersion, the soaking given in the acid alum solution would be sufficient to remove the greater part of the pyro., so that the alkaline hypo. need not reintroduce, or cause the increasing of, the pyro. stain to any great extent. We recommend ammonia in place of soda or potash, as it has the property of holding in solution those insoluble silver compounds sometimes produced by the mutual decomposition between silver compounds and hypo. We trust that our readers may give the method we describe a trial, and report the results. Our own opinion is that it will be a material gain to existing processes, leading to marked improvement in "wet-plate character."

THE PANORAMIC EXHIBITION OF WIDE-ANGLE PHOTOGRAPHS.

One of the most surprising effects obtainable in connection with the examination of photographs is to witness the exhibition of a transparency projected upon a large screen, the scene being then made slowly to move to one side by a continuous, steady, slow motion. On one occasion, upon which we witnessed a display of this nature, when the steady, panorama-like motion had been kept up for some time, and there seemed to be no end to the panorama thus presented, a lantern expert who was present became quite excited and shouted out—"Has the photograph no end at all?"

It is a peculiarity of a very long slide that when it is made to pass slowly across the disc the lenses get somewhat confused. Indeed, to such an extent is this the case that it is impossible even to guess how many diameters of the disc are shown during the transit. If anyone will take a sharp view embracing a very wide angle on a 5 × 8 plate, and then enlarge the horizontal central portion of this to about three diameters, allowing it to occupy two plates fifteen inches long by three and a-half inches deep, the conditions for exhibiting the picture in panoramic style will be perfect.

Two lanterns are necessary for an exhibition of this class, and the pictures must be printed in such a manner as that a portion of the end of one, to the extent of about three inches, should be duplicated in the commencement of the scene on the second slide. Arrangements must also have been made to secure the most perfect registration of the terminating portion of the one and the opening portion of the other slide.

Everything being in readiness, and both lanterns being placed under full light, the lantern "curtain" effect is raised by the means now within the knowledge and at the command of every exhibitor by the aid of the better class of dissolving lanterns, and as the curtain rises the view stands revealed upon the screen. The sliding movement is effected by means of a winch handle, which, when rotated, causes a slow passage of the picture across the lantern condenser. By the time it has reached the end the curtain effect must have been removed from the lantern in which it was shown, and the second portion or continuation slide of the panoramic pair of views substituted for it, care being taken to bring it up to registration mark. When it is seen that the termination of the view has been reached, the light, by a flashing cap action quite unperceived by any of the spectators, is cut off from the one lantern while the other is simultaneously thrown open, the same view still remaining before them on the screen; and here ensues the repetition of the slow movement of the scene across the disc. This continues, with occasional stoppages for explanations as to the nature of the scenes, should such be required, until the end of the long slide has been reached, by which time the curtain slide has once more been placed *in situ*, and the scenic curtain allowed to fall by the means to which we have already referred. No one who has not tried this photo-panoramic system of exhibiting transparencies, or who has not seen it done, can form an adequate idea of the effectiveness of the method.

Skill and tact are required in the selection of subjects properly adapted for this class of exhibition; but there is no inherent difficulty involved in its accomplishment. To produce the negative a lens that embraces a very wide angle and one which defines sharply to the extreme sides of the plate is absolutely necessary, because from the negative thus obtained a transparency magnified three diameters must be produced. This implies a degree of sharpness of which any good wide-angle lens is capable, especially when employed with a small diaphragm.

Among those public exhibitors who may be mentioned with commendation as having acquired a special facility in the display of panoramic photographs of the character described, are Messrs. Brooks and Bridge, who, in their entertainments, frequently avail themselves of this effective manner of exhibiting wide-angle views.

COMBINATION PRINTING.

Last week we explained how transparencies on thin films, such as those of gelatine or collodion, could be successfully utilised in the production of combination negatives, and it was then pointed out how admirably such film transparencies were adapted for combining as a whole several negatives to form a panoramic picture.

The same principle may also be applied in combining different negatives into one to form a panorama, without the intervention of a transparency at all. In this case the glass upon which the negatives are taken must, beforehand, be prepared either with wax or talc to facilitate the removal of the films. The compound film of india-rubber and collodion will be for this purpose found preferable to one of gelatine, inasmuch as a thinner film will suffice, and it will prove an advantage in the printing. After the negatives have been developed, fixed, and dried they are placed on a levelling-stand, then coated with the india-rubber solution, and when the solvent has all evaporated collodion is applied, as we described last week. When the second coating is dry the films are removed and then mounted on a glass plate, being matched in the same manner as in the case of transparencies already described. The slight thickness of the collodio-india-rubber film intervening between the image and the paper during the printing will not practically interfere with its sharpness.

The plan of stripping the films and then joining them may also be made available for obtaining combination negatives of groups, which have frequently to be produced in everyday practice. It often happens that one or more figures are desired to be introduced into an already-taken family group—say an enlargement. Frequently the only portraits available are not of a size to correspond with the other figures in the picture. By the following method such object may be accomplished:—In the first place, an enlarged negative of the group is made and the film stripped off, as already described. This film negative is now mounted on another glass. Then, negatives of the extra figures to be introduced are made of a size to correspond with the others in the group, and likewise stripped. Next, these figures are placed in the position they are to occupy in the group negative, and the film secured to the glass by a strip of gum paper at the edge, or at some place where it will not show in the finished picture. The outline of these figures is then cut out, both through the figure film and the film of the negative beneath, and the pieces set free removed. An accurately-fitting junction is thereby secured, and the combined negative is ready for printing from.

At one of the meetings of the Photographic Club, and to which allusion has before been made in connection with this subject, Mr. Jabez Hughes mentioned a commission he received some few years back. It was to reproduce a large panoramic view in Paris. The original was in three pieces and joined in the mounting, each piece being nearly the full size of a sheet of photographic paper, the picture itself measuring something like four feet in length by two feet in width. The reproduction was required to be the same size as the original, and to be *printed in carbon*. To make the matter more difficult to accomplish, unfortunately the three sections of the picture had faded very considerably and, at the same time, very unequally, each section possessing a widely-different degree of yellowness.

As Mr. Hughes had not the convenience for working the carbon process on so large a scale, he commissioned a London firm* to execute the work for him. The result obtained by them Mr. Hughes characterised as simply marvellous; for, not only was the reproduction better in every respect than was the original (in its

* The Autotype Company, we believe.

then state), but it was really better than it ever had been. It was better than the original then was in the following respects:—The lights were pure and white, instead of being yellow; the picture was of one tint throughout, consequently one section of it did not contrast in colour with that of the next, which would render the joins more conspicuous than they otherwise would have been. Added to this the reproduction was on one sheet of paper instead of being on three, therefore there were no joins in the paper to be seen. It was better than the original had ever been from the following causes:—Instead of the sky being white or of an uniform flat tint, showing the joins of the paper through it, this reproduction was on a single sheet, and delicate clouds had been artistically introduced in place of the white sky.

Mr. Hughes was unable to explain how this result had been achieved; but, at a subsequent meeting of the Club, one of the members explained how this identical picture had been reproduced. With his permission we shall here explain how it was accomplished, as the details of the plan may prove valuable to many of our readers, and it will serve well to illustrate what may be accomplished with stripped negatives.

In the first place, each of the three sections of the picture was copied separately the full size, the glass used being somewhat larger than was actually necessary to contain the whole of the subject in them. In the exposure and development of these negatives great care was bestowed on making them of identical density, or as nearly as it was possible to do this. The negatives being finished, a piece of thin paper coated with gelatine was squeegeed down upon the collodion film, where it was allowed to dry. When dry the paper was stripped off, bringing with it the collodion bearing the image. The paper was then rendered translucent with wax or similar material. The centre section of the three was now firmly secured, at the top and bottom, on a plate of glass the full size of the picture, with slips of gum paper. Then one of the side sections was adjusted in position and secured in the same way, and, finally, the third. As the glass used for the negatives was larger than each of the sections, it included of course a portion of the next one, and this permitted the overlapping portion of the subject to be used for securing an accurate adjustment, in the manner we explained last week.

When all three negatives were thus arranged in position, the films at the junctions were cut through with a sharp knife and the loose pieces removed, thus obtaining an accurately-joined negative on the large plate of glass. Next, the whole of the sky was blocked out, so that it printed quite white. After printing the subject, clouds, which were painted on a second piece of glass, were printed in. It may be as well to mention that in mounting the stripped negatives on the large glass the collodion film was placed uppermost, which enabled the print to be made by the single transfer process, as well as securing a crisper image when printed. From the description here given it will be seen that an apparently extremely difficult undertaking was, in reality, accomplished by very simple means.

In this and the foregoing articles—which, by the way, have extended to a much greater length than we anticipated when we commenced them—we have not attempted to describe all the various methods, or "dodges," by which two or more pictures may be combined into one. A volume would almost be required to do this completely. Sufficient, however, has been said to indicate how any person with ordinary ingenuity may adapt or modify one or other of the methods described, so as to accomplish almost anything that may be required in the way of combination printing.

PHOTOMICROGRAPHY.

The Polariscope.—This is useful in photographing some of the delicate crystallisations that form gorgeous objects under the microscope, also in detecting minute striæ, differences of structure in the transparent parts of sections of mineral rocks, and in organic bodies. The Nicol prisms should be large. The analyser can be set either near to the objective or over the eye-piece; the polariser placed below the object and used either with or without the substage condenser; the prisms crossed to give requisite differentiating appearances, the light and field being variously affected according to their position, using a low eye-piece. If a selenite film be placed beneath the object, select it of such thickness as will furnish the best contrast, photographically, in the complementary colours between field and object, or its different parts. Various tints are often rendered by various tones in the picture, showing structural differences.

Oblique Illumination.—This is less easily managed than with central light. Generally some substage arrangement, as used by Dr. Woodward in photographing difficult test objects, is required; but for ordinary work, and artificial light, there is a choice according to the end in view between the parabolic condenser and truncated lens, Wenham's reflex illuminator, semi-disc illuminator, Nachet's prism of 35°, Amici's prism, spot lens, Reade's prism and "kettledrum," Woodward's prism, achromatic condenser with central stop, or oblique aperture, a radial substage condenser, or a long-focus objective, set at the proper angle to the under surface of the slide. The selection must depend on the substage arrangements and the possible position of the source of light, the chief object being to obtain detail without *too heavy* shadows.

Professor Abbe says:—"With the nearly hemispherical immersion plano-convex lens of 6—9 m.m. radius, the ordinary concave mirror, turned slightly outside the axis of the microscope, will then give cones of rays of any degree of obliquity which may be desired." "When the detail in the real object appears in the form of striation, groups of lines, &c., a given angular aperture always reaches much finer details with oblique than direct illumination, and this irrespective of the circumstance that the constitution of the object admits or excludes the possibility of shade effects." (*M. Mic. Jour.*, 1875, p. 200.) Again: "the increased effect of oblique illumination depends solely on the inclination of the rays towards the axis of the instrument, and not upon the oblique incidence of the light on the object." A very interesting article on solar, sky, and cloud light, as reflected from the ordinary mirror of the microscope, will be found in the *J. R. Mic. Soc.*, 1880, p. 742. Speaking of spherical aberration, Professor Abbe says:—"There is no doubt that on balsam-mounted preparations striations up to 5,000 lines per millimetre (125,000 per inch), would be readily resolved by an incident pencil of the utmost obliquity, and still finer photographically." (*J. R. Mic. Soc.*, 1879, p. 822.) "The image of an object with very fine detail being, in fact, formed of two images—an absorption image and a diffraction image—the ordinary theory that explained the formation of the image by the geometrical method is fallacious." (P. 651, 1872, *loc. cis.*)

Artificial Methods of Illumination.—Besides the single-wick paraffine lamp there are others with multiple wicks. Care is needed in using these, or the shadows from the space between the wicks may interfere with perfect illumination of the object. There are also the electric, oxy-hydrogen, oxy-calcium, and magnesium lamps—each useful in about the order named. Dubosq's and Browning's electric, and Swan's incandescent lamps, are of excellent service; but the battery or dynamo current required for constant use is at present a source of trouble. Swan's is, perhaps, the easiest of application, as it can be approached very near to the object, the narrow side of the carbon thread being turned to the object-slide, care being taken that the small globe is of good figure, clear and without striæ. With the others the condensers should be arranged so as to give a beam of parallel light, or a cone of long-converging focus before reaching the achromatic condenser. Solomon's magnesium lamp is useful; but, wanting this, a piece of magnesium wire can be burnt, being steadily projected a little obliquely downwards, at the rate of consumption, through an aperture in a thin plate of iron, opposite the axis of the substage condenser. Dr. Maddox used a little apparatus for this purpose, which is figured in Dr. Beale's *How to Work*, &c. A small ball of zinc shavings was proposed by Mr. Wenham, and, if mixed with fine magnesium wire, affords a fair light. To save expenditure of wire, previous focussing, &c., can be made by the use of the paraffine lamp, care being taken to ignite the wire in the same position as the flame occupied.

Heliostats.—In addition to those already named are Prazmowski's, Dr. Willis's "simple form" (which appears very commendable), Keith's, Browning's, and Johnstone-Stoney's—described at the meeting of the British Association, Exeter, 1869

Applicability.—Besides furnishing negatives for prints of minute objects, such as can be seen in the library of the R. Mic. Soc., in different journals, and in works on microscopy, some books have been entirely illustrated by its use, and it is of considerable value for lantern slides. Lately we have seen prints obtained by it of Dr. Flögel's sections of the *diatomaceæ*, also of Möller's type plate of *diatomaceæ*, as photographed by Mr. Walmsley, U.S., having the names of the diatoms photographed beneath them on the slide—truly a triumph of photographic skill; and we are able today to refer to its great utility, as furnishing many of the beautiful illustrations to Dr. Sternberg's highly-important work on the "Bacteria," second edition, just issued.

An attempt has been made to indicate some of the most useful methods in photomicrography, but for want of space many plans have been omitted, and to the authors every apology is offered. In conclusion: the references have been considerably extended beyond those which relate to photography, in order to furnish information upon cognate subjects—many of them valuable papers bearing on useful apparatus and the higher branches of microscopy. We now leave the subject in the hands of those interested, and trust the new year may, through the aid of this imperfect sketch, bear further witness to the utility and progress of photomicrography.

(To be concluded in our next.)

OUR attention has been called to an inaccuracy in our article on *English and French Weights and Measures* at page 51 of our present volume. In the last paragraph on that page, if the sentences commencing on the fifth line be read as follow all will be correct:—"For a very rough estimate Fahrenheit degrees may readily be translated to centigrade by subtracting thirty-two and *halving* the remainder. Complete exactitude will be found if this result be *increased* by *adding* its *one-ninth* part." Or centigrade degrees may be converted to Fahrenheit by doubling the former and subtracting from the result its tenth part. The place in the scale will then be found by adding thirty-two to the figures obtained.

WHEN in conversation with Mr. William Brooks he mentioned, with reference to the communication from Mr. G. H. Johnson, of Bridgeport, Conn., U.S.A., which appeared in our issue of the 4th ult., that there must have been some misapprehension existing on that gentleman's mind when, on the subject of transparencies, he writes—"I have been trying some of Mr. Wm. Brooks's collodion emulsion for this purpose." Mr. Brooks is not aware of having sent Mr. Johnson any of his collodion. He did, however, send him a letter on the subject, in which it is not unlikely he may have explained the principles upon which he constructed his collodion emulsion, or may even have suggested the trying of some particular formula; but he has not given full or detailed particulars of working either to Mr. Johnson or any one else, as he has reserved this for another purpose.

ON DIT that a few capitalists are going over to the United States, accompanied by several experienced practical dry-plate makers, to start dry-plate works on a very extensive scale. It is understood that Mr. W. Irving Adams, the Managing Director of the Scovill Manufacturing Company, is to be the president of this new company, or, at anyrate, that the presidency is to be offered to him. The new company will have special advantages in the purchase of glass, gelatine, &c., which will at once give them a leading place in the market.

ONE cause of the large number of experimentalists in microscopy and photomicrography in comparison with that of astronomical observers must be found in the ease with which the microscope can be manipulated, while the use of the telescope involves not only an entire abandonment of all "arm-chair exercise," but often a submission to considerable personal inconvenience. Thus, in obtaining a photograph we, a little while ago, described how the Rev. T. E. Espin had to perform the work lying on his back for the greater part of an hour. It seems probable, however, that a pleasanter state of things may exist for the astronomer of the future; for, at a recent meeting of the Physical Section of the

Royal Dublin Society, our world-famous contributor, Mr. Howard Grubb, read a paper on a *New Form of Equatorial Telescope*, in which the observer is placed in more favourable conditions, and may, indeed, be as comfortable as a microscopist. He described some small instruments he had actually made, and showed upon the screen a design for a colossal instrument, in which all the optical and large mechanical parts were in the open air except the eyepiece, which was situated in a room on the top story of a house. The observer was represented seated in an easy chair, beside which were two handles controlling hydraulic machinery, and by which all the movements of the great telescope were effected.

It appears that Mr. Grubb's new arrangement is estimated to be producible at a cost of only about one-third the usual expense, while the only approach to a similar convenience of working—the French bent or elbow equatorial—requires extreme complexity or arrangement in working, and entails enormous expense.

A few years ago the great question of "swallow-tail," or frock coats, at the Photographic Society's *conversazione* almost raised a revolution; and lately some one proposed to convert the occasion into a ball. We commend to the consideration of the gentlemen interested in this question the example of the Painters' Societies. According to the *Athenæum*, some members of the Society of Painters in Water Colours are attempting to give a social character to the body. "A similar movement has stirred the Institute of Painters in Water Colours; and partly with this object, and partly in order to augment the funds of their free schools of art, it has been resolved to hold an artists' costume ball in the magnificent Prince's Hall of the new buildings in Piccadilly. This entertainment will be opened with a procession, illustrating the different epochs of art, by ladies and gentlemen dressed in character and arranged in several groups!"

Should this hint of ours fructify, the proceeds might well be given to swell the funds of the Photographers' Benevolent Association.

In reference to the subject of dangerous chemicals, noted at the close of our *Transatlantic Jottings*, we may point out the highly-dangerous character of acid bichromate of potash, so often employed for electrical cells, and so useful for cleaning glass, as first recommended many years ago in our columns by our esteemed contributor Mr. M. Carey Lea. The powerful toxic character of this substance (which is, when not taken internally, most corrosive in its action upon the skin) may be judged by an account from France of the poisoning of two men who had swallowed a quantity of it. The men thought the pretty-coloured solution of acidified bichromate was Malaga wine, and they swallowed a wineglassful of it. Together they seem to have imbibed only about five grammes of bichromate; but the draught was a fatal one.

Our readers may remember that the action of light upon paper in causing the discolouration of certain kinds was alluded to in our columns some time ago, when an alleged fading of carbon prints was brought into prominent notice; it will, therefore, be interesting to learn how to test a sample of paper to ascertain if it contain any wood pulp or fibre. We read that either a solution of sulphate of aniline in water or a mixture of one part of sulphuric with three of nitric acid can be used for the purpose. The presence of wood will be shown by the immediate production of a yellow stain as soon as the liquid is applied, the stain becoming deeper and deeper according to the proportion of wood present.

We observe that Mr. Richard Walzl, of Baltimore, Md., U.S.A., has commenced a new monthly photographic periodical, entitled *Walzl's Monthly*. Its page is of the same dimensions as that of The British Journal of Photography, and, unlike the other American journals, it has no cover. It contains a varied amount of matter interesting to photographers.

Talking of the covers of American journals, we observe that the New York *Photographic Times* commences a fresh volume under a new cover. We must confess, however, that we preferred its appearance in its old garb, the chaste richness of which had secured for it the highest encomiums of more than one competent judge in such matters. True, the outside of a publication is not an invariable criterion of its contents; so let us hope that our contemporary, if there be any falling off in appearance, may make up for it in the greater value of its matter.

The dark colour assumed by alkaline pyrogallol has been a[illegible] to the production of purpurogallin; but, from experiments performed by Signor E. Rotondi upon the electrolysis of solutions of pyrogallol acidulated with sulphuric acid, he is inclined to think that the above-named body is not the direct production of the oxidation derived from an intermediate compound.

According to the *Bulletin de la Société d'Encouragement* M. Decaux has been making a series of experiments upon the action of sunlight and the electric-arc light upon colours used in dyeing and in painting with water colours and oil colours. His deductions agree in the main, though not entirely, with those obtained by former investigators. Colours for painting in water and oil he divides into the absolutely permanent, the moderately permanent, and the fugitive. He finds that in water colours all the most beautiful reds—carmine, crimson lake, most madder lakes, and vermilion—fall under the fugitive class. If mixed with oil the madder lakes rank as moderately permanent.

In view of the vast number of coloured photographs—good, bad, and indifferent—now produced, it behoves those who cater for the public in this direction to look carefully at their colour-boxes. Carmine and crimson lake are, the one so brilliant and the latter so readily used, that, despite their reputation for fugitiveness, they are, we are afraid, employed too frequently; but the madder preparations have a far higher reputation, and they are not generally considered as fugitive colours, yet, according to M. Decaux, they are all bad alike. However, in this respect, provided a permanent photograph be employed for colouring upon, the photographic colourist and the water-colour painter stand upon the same footing.

DEVELOPING GELATINE NEGATIVES.

In reply to the communication of "Questioner," in last week's Journal, I will endeavour, as briefly as possible, to state in what respects I have found sulphite of soda a disadvantage when used with alkaline pyro. development for gelatine negatives. I am quite aware that my opinion, whatever it may be worth, is at variance with the present conviction of many careful and experienced operators; it is, nevertheless, the result of a series of comparative trials made with a view of utilising the advantages, if any, of sulphite of soda as an aid to the perfect development of gelatine negatives.

If I understand rightly, the advantages claimed for the sulphite are—first, the absence of the usual non-actinic colour of the deposit; and, secondly, the facility of obtaining clear glass in the shadows of the negative.

As regards the first claim: the colour is undoubtedly totally different, the deposit being of a cold grey or black tone, instead of the usual warm brown given by normal pyro. development. A negative of the latter kind may not be so pleasing to look at when viewed as a transparency; but, inasmuch as it is only used as a means of producing a print—presumably on chloride of silver—the alteration of the colour will only prove an advantage provided the negative has been developed to full printing density at the first operation, otherwise, unless the negative be intensified, the print will be weak and flat, and wanting in the brilliancy which would be given by a more non-actinic colour. For this reason I find it better in practice to retain the warmer colour in the first instance, reserving the power so easily exerted of changing the colour of the deposit to any required extent, according to the density of the negative, after the completion of development, thus securing a double chance of obtaining negatives of uniform printing density.

With respect to the second claim—namely, clear glass in the shadows—there is no doubt that the addition of acid sulphite, being a powerful restrainer, does give the facility of obtaining bare glass in the least-exposed portions of the film; but, however valuable this quality may be in a positive transparency, such as a lantern slide, it is utterly unnecessary as one of the printing qualities of a negative, provided there is a proper gradation of tone from the highest lights to the deepest shadows. In fact, it is well known that a very large majority of the finest silver prints ever produced from negatives by any process, wet or dry, have been made from negatives having little or no bare glass in the shadows.

Your correspondent calls special attention to this one important quality above all others which constitute a perfect negative, namely, true gradation of tone. He also points out that this depends to a great extent upon the plate. It is, perhaps, not generally known to what extent this is true of different makes of dry plates (which vary as much in their capabilities of giving true gradation as wet collodion at its best and at its worst); but, even with the most perfect plates, it is precisely in this respect that the sulphite developer has failed in my hands to give satisfactory results. It seems to cut off a little at either end of the scale. With normal exposure a little of the detail in the deepest shadows is lost, while, if the exposure be slightly increased and the development pushed to obtain the required density, the delicate half-tones next the high lights are sacrificed. The loss is in some instances very trifling, and in small, well-exposed landscapes would probably be hardly perceptible; but in portraiture or large pictures with much half-tone the difference is at once apparent. Sulphite of soda in the pyro. developer seems to act much in the same way as the addition of gelatine to the iron developer for wet plates. This much-vaunted improvement was equally fashionable for a time some years ago, but has long since been discarded except for special work. I venture to predict a similar fate for sulphite of soda at no very distant date. Already many of our best and ablest workers have discontinued its use, chiefly for the reasons stated above.

I have omitted to mention the preservative properties of the sulphite in pyro. solution. In this respect its action seems perfect; but the same result is effectually obtained by the use of glycerine and alcohol, or a trace of acid in the aqueous solution, without the disadvantages of the sulphite of soda. B. J. Edwards.

DR. EDER'S RECENT RESEARCHES.

The properties of the ferricyanide of potassium, in combination with gelatine, discovered by Dr. Eder, and mentioned by Mr. Bolas at the first of the series of Cantor lectures, may possibly cause a complete revolution in carbon printing, and most processes of a kindred nature, where the gelatine has to be washed away, as in the Woodburytype, stannotype, &c. There are, doubtless, many points to be solved — such as relative sensitiveness to light, principally—although, not having had any experience with this combination, I should imagine that, if insolubility of the gelatine occur on mixing with the ferric salt, there would at once arise a difficulty in getting either paper or glass coated with the mixture. But if it could be employed, as are now sensitive carbon or stannotype tissue, there seems to be no difficulty in its use.

A complete reversal of all the processes would naturally occur. The carbon process would require a positive, and the stannotype a negative to work from, thus completely changing the existing order of things. In the latter process all that would be required would be to keep sheets of plate glass coated permanently with gelatine and sensitise as required for use, to expose under a negative, and wash away the parts rendered soluble by light, coating, when dry, with tinfoil, as usual. No reversal of the image would take place, as the surface image from the negative would naturally be reversed, and brought right again in the print. This is a most important feature in all photo-mechanical processes, and formed in the early days of the Woodbury process a serious drawback, until by accident a relief was laid with the wrong surface in contact with the lead—turned inside out, in fact—with no apparent difference in the resulting prints. Since then this method has been adopted in all Woodbury printing, except where film or reversed negatives were handy. In what Mr. Bolas termed the first stannotype process (although the name was only given to the later) the same difficulty appeared, all prints being reversed, which called forth the remark from a celebrated German firm that this fact took all the cream off the system. This additional reason to those given by the lecturer was the cause of its abandonment. Walter B. Woodbury.

DARK ROOM ILLUMINATION.

Since writing my last article, which was based on theoretical grounds only, I have made some experiments which, I may add, have been very carefully conducted. I considered I was in duty bound to Mr. Starnes to follow up with experiment what I had predicted on theoretical grounds.

It will be remembered that I challenged his statement that light from an orange surface gave almost as much deposit on a gelatine plate as light from a blue surface; and, further, I pointed out that comparisons of this kind were of little account if the brilliancy or photometric value of the light were not taken into account. Mr. Starnes thinks this to be of secondary importance in connection with his lamp. Now, I really do not wish to see this matter getting into hopeless confusion, as it undoubtedly will if the importance of a necessary factor in the solution of the problem be not recognised.

I insist that the photometric power—in other words, the sight-giving power—is one of the things that must be determined if comparison is to be of any value at all. It does not matter whether light proceeds from glass, paper, velvet, wood, ochre, or any other substance or combination of substances, or whether from an opaque or transparent body or a combination of opaque or transparent bodies. What we have to do with is the light after it has passed away from its source. Mr. Starnes must surely accept this as self-evident, and admit that it is as applicable to his lamp as to any other lamp. We must, therefore, reduce all kinds of light, from whatever source, to a level as to sight-giving power before any comparison as to actinicity is made; or, conversely, we may reduce to a level of actinicity before the sight-giving comparison be made.

I repeat that if we are to save this subject from confusion the photometric value must be as carefully determined as the sensitometric value. So much stress do I lay on this point that sensitometer figures I simply lay on one side as valueless unless accompanied by photometric figures. A sensitometer costs a comparatively large sum of money compared with the cost of a standard candle. Is it not a pity that figures obtained by an expensive instrument should be valueless for want of a candle?

The experiments I have completed were carried out with the aid of an improvised photometer. The reflecting surfaces were prepared in the following manner:—I procured the dry pigments used for the preparation of lithographic inks and made up a quantity of each in separate mortars with a small quantity of starch—just sufficient to prevent the pigment being rubbed off the finished surface. I now brushed pieces of millboard with the pigment and allowed them to dry. These surfaces, when examined with a glass, were practically identical, excepting the tint. My photometer was simply a box with an arrangement enabling me to vary the distance of the light from the coloured surfaces in in such a manner that I could make the photometric value of a given area equal to any arbitrary standard. I used the shadow method of determining the equality of the light. When actually carrying out an experiment I exposed a plate—one half to one light and simultaneously the other half to the other light, the edge of a dark septum dividing the plate. Comparing blue and orange surfaces I could not get even an approach to Mr. Starnes' results. Invariably the half of the plate expossd to the blue light flashed out under the developer and gave a very dense deposit, while the other half remained clean or gave only a trifling deposit.

I extended the experiments to red and orange, and must, in justice to Mr. Starnes, say that here the result was exactly as he has stated. Instead, however, of allowing this to shake my belief in the value of that beautiful instrument, the spectroscope, as applied to *practical* photography, I turned to it for an explanation. On applying the magic slit and prism I was not at all surprised to find that the particular red I was working with was of a very compound nature indeed. I have little doubt but the red employed by Mr. Starnes would be found to yield a complex light. It would, indeed, be worth recording were red rays found more actinic to silver salts than yellow or orange.

Re photographing the spectrum: what difference would Mr. Starnes expect to find between a spectrum photographed direct and one photographed after being allowed to fall on a *white* screen? Mr. Starnes says this would be an interesting experiment, and would have a most important bearing on the subject of reflected light. May I ask—In what way?

In speaking of a proposal of Mr. W. E. Debenham's to paint the interior of the lamp of a chrome yellow Mr. Starnes says:—"In each case I was very much struck with the rapid falling off of the actinic power of the light the further the plate was placed from the lamp compared to the loss of luminous power." *Impossible*, otherwise a hitherto well-established theory must terminate its day of usefulness. Light diminishes inversely as the square of the distance from the source. Mr. Starnes is struck with the fact that, although this may be photometrically true, yet it is not so photographically. In other words, that in the passage through a small column of air the more actinic vibrations are to a great extent lost by absorption, dispersion, or by other more occult means, and that the law of inverse squares does not hold good so far as these rays are concerned. There is some trouble here, I think, for Mr. Starnes.

Next week I propose to give a method that should, I think, settle once and for all the vexed question of dark-room illumination. I am at present working the matter out at such odd hours as I am able to snatch from business. As to Mr. Starnes' communication, which appeared in your issue of February 1st, entitled *Actinic Force* versus *Colour*, I will possibly have something to say. At present my feeling in regard to it is that at last the edge of a formidable morass has been reached. I have little wish to banter, but this article is simply crushing. The way Mr. Starnes makes a tilt at well-established theories, levelling them in one fell swoop, shows, to put the matter quietly, that he has the courage of his convictions.

G. D. Macdougald.

STANNOTYPE.

No. II.

The first step towards the production of the stannotype printing mould consists in obtaining a transparency from the negative to be reproduced. As the success of the subsequent operations rests very materially upon the character and quality of the transparency, the details of its production may be dwelt upon with some minuteness. Any process may, of course, be adopted; but in view of the special requirements of this particular case the carbon process is, perhaps, to be preferred on the score of convenience, as it affords considerable scope for modifying the peculiarities of different negatives. In fact, the necessity for this intermediate transparency becomes under the circumstances an advantage rather than otherwise.

The principal requirements in the transparency are sufficient vigour to withstand the somewhat long exposure to light, which is necessary to produce sufficient depth in the relief, combined with due gradation in the half-tones and perfectly clear glass in the highest lights. In fact, when laid upon white paper the transparency should exhibit the qualities of a good, strong positive. The necessity for clear glass in the highest lights must be insisted upon, for reasons that will be made apparent in a later stage of the description; suffice it to say now that a positive, however perfect it may be in its gradations, but wanting in this one element of clearness in the high lights, is useless for the purpose in question. The capability which the carbon process presents for securing this class of result from almost any kind of negative is beyond question, and it is for this reason that it is specially recommended; though with careful manipulation it is probable some operators will be able to produce satisfactory results by other means.

As the exact effect desired in the transparency is gained in a great measure by intensification or "toning" by chemical means after development, the ordinary portrait tissue is, as a rule, preferable, owing to its comparatively thick film of gelatine. A tolerably strong sensitising bath should be used—not less than four per cent. of bichromate, five or six per cent. proving, in the majority of cases, advantageous, as with this strength it is possible to obtain an image full of detail in every grade of the picture, from the highest lights to the deepest shadows.

Such an image, consisting, as it does, of varying thicknesses of gelatine (the colouring matter may be to a certain extent ignored), is capable of almost unlimited intensification in exact proportion to the gradations actually existing by any of the methods of staining the film usually adopted, and this without any risk of degrading the highest lights. As these are, or should be, represented by "clear glass"—that is, an absence of gelatine deposit—there is nothing to be stained, and so the intensification may be pushed to any extent without danger, provided a suitable collodion be used as the substratum.

For this latter purpose any good "enamel" collodion is utilisable, but it is needful to ensure that it dries without opalescence. It is better that the collodion film be not too thick. Its only object is to prevent the washing away of the delicate details of the higher lights, no further good effect being secured by a thicker film, as when it is needful to strip or transfer the picture after development. The thicker collodion film, moreover, offers greater chance of staining in the subsequent intensification of the carbon image.

In sensitising the tissue it should be immersed in the bichromate solution for from three to five minutes according to temperature, and then placed in contact with a sheet of plate glass and "squeegeed" in order to remove the excess of solution. It is then to be suspended in an airy place—preferably in a warm room—in order that it may dry as rapidly as possible. In fact, every precaution should be observed to prevent the chance of partial insolubility occurring, either from prolonged exposure in a moist state or to an atmosphere contaminated with deleterious gases. Such partial insolubility would, it is needless to say, be fatal to absolute clearness in the high lights unless under a high-temperature development, when the delicacy of the half-tones would be jeopardised. As soon as dry the tissue should be stored in a dry place under pressure in the flat state, or else in a metal case, rolled up with the gelatine side outwards. Either method will not only preserve the sensitive film from atmospheric influence, and consequently retain its solubility, but also keep it in a better state for securing perfect contact with the negative.

In printing it is scarcely needful to say that the "safe-edge" is indispensable. This should be rather wider than usual—if possible about a-quarter of an inch—in order to allow a narrow border to be left between the actual picture and the "safe-edge" used in the next operation.

The necessity for this, as well as the absolute clearness of the highest lights of the transparency already referred to, may be here explained. In the ordinary "Woodbury" printing relief—that is, the mould formed by pressure of the gelatine relief *(made from a negative)* into a plate of soft metal—the "safe-edge" is a border which practically represents the highest lights of the picture, and, as such, gives value to the whole of the gradations by limiting the depth of the layer of gelatine which forms the print. But in the case of the stannotype printing surface, which is formed by direct printing *from a positive*, the ordinary "safe-edge" would represent the deepest shadows of the print, or, in other words, the extreme *depth* of the printing mould. This, it is clear, would leave the surface without planimetry, and the gradations of the picture without any definite value. To overcome this difficulty it is only necessary to print the *transparency* with a rather broad "safe-edge"—that is, with a certain margin of practically clear glass. In using the transparency for the subsequent production of the printing mould it is again provided with a "safe-edge," but narrower than the former one, so that a border of clear glass is left between it and the picture proper, and this will form the highest portion of the printing surface, and, therefore, the highest light of the picture.

It will be plain from this why the perfect clearness of the high lights of the transparency is insisted on. If these be slightly tinted, though in perfect relation to the rest of the picture, while the "safe-edge" or inner margin is clear glass, the result will be that the printing mould will have a border slightly higher in relief than any other portion of its surface; and, consequently, that, in printing, every portion of the picture will possess more or less of a tint in proportion to the difference between its highest lights and clear glass. The printing surface must, in fact, be a *dish*, the edges of which are formed by this border resting between the "safe-edge" and the picture.

Nothing particular need be said of the operations of printing and development. These are performed in the ordinary manner for carbon printing, care being taken not to over-expose to any appreciable extent so as to form a deposit in the extreme high lights. Let the development be conducted with especial care and with water at as low a temperature as can be conveniently worked, finishing, if needful, at a higher temperature to clear the lights.

At this point the opportunity occurs of intensifying or modifying the character of the transparency. The picture now consists of a cast, so to say, in slightly-coloured gelatine, the different gradations being represented by varying thickness of gelatine. If these gradations be in due proportion one to another—it matters little whether the image be generally dense or otherwise—it follows that the mere colouration of the gelatine film will increase the intensity of the image in exact proportion to the already-existing gradations. This can be readily done by means of a ten-grain solution of permanganate of potash applied for a minute or so.

If after washing thoroughly the image is not yet dense enough, let the film be dried and then again submitted to the action of the same solution. This is preferable to the longer continuation of the treatment without drying, which only tends to stain the underlying collodion film. If the further application of the permanganate solution fail to give sufficient density a three-grain solution of gallic acid may be used followed by a solution of perchloride of iron or any ferric salt; the sulphate or potassio-sulphate answers well. The gallic acid solution, if long applied, will probably *reduce* the density, but the subsequent action of the ferric salt will more than restore the loss.

Nothing remains to be said on the subject of the transparency, in describing the production of which it has been assumed that the reader is familiar with, at least, the general manipulations of the carbon process. Should any points have been left in doubt they will be explained in our *Notes and Queries* column.

ACTINISM AND WAVE-LENGTHS.

The paper by Mr. Herbert S. Starnes in last week's number of the Journal was a very interesting one, particularly as it opened up new directions for thought; but some of the statements in it are so contrary to the generally-accepted theory of light that they should not pass without being challenged.

In speaking of the effect on light in passing through red glass he says:—"The red glass has brought the various wave-lengths of the white light all to one length—I ought rather to say nearly to one length," &c. Now this infers, or rather asserts, that the component parts of white light are changed in their character by their passage through the red glass, and that the blue rays, &c., have their wave-lengths altered and are turned into red light. This is certainly not what is usually considered to take place. The red glass does not alter any wave-lengths, but merely acts as a sort of filter, stopping the passage of nearly all the rays except the red.

In the next paragraph there is a most extraordinary statement, namely, that the "*combined wave-lengths of yellow and green are more than that of the red alone.*" If this were so, then we should get *no light* at all; for, as the wave-lengths were longer than that of red, they would cease to have any effect on the eye, and, in fact, would become part of the heat waves of the invisible portion of the spectrum beyond the red. We must look to some other theory than this for the efficiency of Mr. W. E. Debenham's plan of using a combination of green and yellow in the dark room.

Further on Mr. Starnes says:—"If we use quartz lenses the violet rays are less powerful to withstand actinic force." To me this is a very ambiguous sentence. Would Mr. Starnes explain his meaning more fully? There are several other portions of his communication that appear to be quite new departures—notably that the addition of silver bromide (presumably a slow one) to boiled gelatine will give a rapid emulsion. I must experiment in this direction. W. Horseman Kirkby.

TRANSATLANTIC JOTTINGS.

Our readers may remember the account (extracted from the *New York Times*) we gave last month of the unfortunate photographer whose camera was smashed by a supposed criminal in tow of a police officer. "Who's to pay?" said the witty writer of the paragraph in question. Mr. Norman Coe, the photographer concerned, writes to say that, so far from the slight *contretemps* in question having prevented his taking a picture of the too vivacious captive, he, by means of a specially-quick dry plate, did obtain a likeness. Although surrounded as he was "by some of the keenest-eyed detectives in New York," no one but himself and his assistant knew when the picture was being made.

Perhaps he used Mr. Eakins's drop shutter—one of the neatest ideas yet propounded in regard to quick shutters. Mr. Eakins has a shutter to uncover and another to cover the lens, and he actuates them as follows:—"Two equal weights attached to cords of different lengths were dropped simultaneously. When the weight on the short cord had fallen as far as the cord allowed the tension released a slide which uncovered the lens. The exposure continued while the other weight was falling. When the end of its string was reached it, in turn, released a second slide, which covered the lens." By varying the length of the second cord Mr. Eakins is said to be able to vary his exposures from a-quarter to one-hundredth of a second.

According to the *Philadelphia Photographer* (which, by-the-bye, is celebrating the commencement of its third decade) the New York police have got hold of a band of scandalous impostors, who, trading on the want of business knowledge of young ladies, have been netting large sums by charging one or two dollars for imparting to their victims the secret of "electrographing" for colouring photographs, and enabling large sums to be thus earned. The very largeness of their trade aroused suspicions and led to their apprehension, from three to seven hundred letters being daily received!

Photographic journalism in America would appear to be more trammelled than our own, if we are to judge by the reply of the editor of the journal first named to the request of several photographers that he should criticise more fully the pictures exhibited at the national exhibitions. He would, he jocularly says, "be compelled to move his *sanctum* a dozen or more stories higher, barricade the doors, place Gatling guns and revolvers in position, and would tremble like an aspen leaf for months after the work had been completed."

According to the *Photographic Times* (New York) some consternation is likely to be caused in the ranks of photographers by a recent decision of the postal authorities, which will result in increasing the postage on photographs by one hundred per cent.—that is, from two ounces for a halfpenny to one ounce.

The Philadelphia Photographic Society has had before it—and almost at the same time as the Photographic Society of Great Britain had a similar paper by Mr. Jabez Hughes—an interesting sketch of photographic progress in America. There is a droll account of the inception of the Philadelphia Society, which, we read, "was born at 615, Walnut-street, in December, 1860, when some twenty-five gentlemen met at the house of Mr. Constant Gillon, the first president. Although the gentlemen went there with their hearts full of the subject the whole evening passed by without its being broached at all, the host expecting the visitors to mention it first, and they looking to him for a start. *Yet a deal of thinking was done.*"

The *Photographic Times* asks why are so many operators given to adding an acid to the alkaline developer? It says—"Sulphurous, sulphuric, nitric, phosphoric, and all imaginable organic acids have been suggested, and were, in reality, used by some of the best operators and amateurs." We presume it is because the function of the acid is not rightly understood. The place for the acid is in the solution of pyrogallic, and its use is to keep the latter from becoming discoloured. When it was first employed for that purpose a large proportion was used; but, as a well-known writer in our own columns pointed out, a few grains of citric acid to the ounce of pyro. was amply sufficient to attain the required end.

We can scarcely agree with the writer in that journal who, in the same article, says the utility of sulphite of soda in the developer, "to say the least, is problematic—at anyrate it is not distinctly proven." Now, if there is one thing more than another capable of distinct proof it is the great utility of the sulphite in preserving the negative from becoming discoloured by the pyro. solution. We imagine the question intended to be called doubtful is as to whether the addition slowed the plate or not—a question that is subject of doubt.

We learn from the same journal that Mr. W. H. Sherman, of Milwaukee, has for a long time been collecting a series of negatives of pictures of the old masters, which he is now arranging in series for the study and information of artists and others who are interested in art. An immense demand is (and we should think justly) predicted for them. We do not know to what extent they will compete with the magnificent collection of the Autotype Company, but the idea is worth commending to the notice of that enterprising body as to whether a specially-selected number of their works might not be printed from and published *en bloc* at a price within the reach of all. Their permanency would be a great point in their favour.

Our transatlantic cousins seem to be rather behind the day in carbon printing, if we are to judge from the account of a meeting of the Photographic Section of the American Institute. Mr. Roche was delivering a lecture upon carbon printing, illustrating it with demonstrations of developing the film. The audience seemed to think the print came by some sort of conjuring, for we read that the President said—"There seems to be a little sleight of hand, Mr. Roche. They think that by some trick or device you have put the picture on the glass. How is the picture made?"

We will conclude our *Jottings* for the month by extracting from *Anthony's Bulletin* an account of the accident drawing attention to the care that even with the simplest chemicals should be taken in all photographic studios:—"Mr. W. D. Gatchel had a very narrow escape from death a few days since. He had been in the habit of drinking a mineral water, and kept it in a liquid ammonia bottle. By some oversight of a clerk a bottle of this fluid was put where he generally kept the water, and he took a portion of it before discovering the error. By prompt measures his life was saved, but for over a week he has been on a sick bed, not able to swallow anything. He is now in a fair way of recovery, but it will be some time before he will be enabled to fully resume his daily duties."

PHOTOGRAPHY AT THE SEAT OF WAR.

The recent intelligence from the seat of war in Egypt, giving details of the defeat of Baker Pasha, also embraces a notification that among the officers missing are the two photographers who accompanied the Egyptian army into the Soudan.

The *rôle* enacted by photographers in giving scenic representations of incidents full of eventful interest is replete with value not only to the general public, but also to geographers and ethnologists, and likewise to students of military science in an especial degree. The accuracy and almost inspired skill with which a clever artist will depict a *rencontre* between two forces ethnologically divergent, one of them adopting different arms and different modes of warfare from the other, elicits admiration, which, however, is sometimes tempered by the surmise that will intrude itself—How would such a scene have been rendered by a photograph instead of by a drawing?

We are not at present aware of photography having been actively associated with military operations previous to the Crimean war, when Mr. Roger Fenton, aided by Mr. Marcus Sparling, both since deceased, paid a prolonged visit to the military head quarters with a complete outfit for taking photographs by the wet collodion process; nor are we aware of any photographs of scenes of active warfare having been obtained by these gentlemen, as their operations were mainly confined to the taking of portraits and groups of the officers of distinction.

It was not long after this, however, ere photographers in other parts of the world were to be occasionally found taking scenes on the battlefield, and some of these were truly ghastly from the stern reality of the facts thus photographically depicted. No room for indulging in artistic licence there, nor for the introduction of any effort of the imagination! Shells seen in the act of bursting, or their dire effects as witnessed a few seconds after bursting; strong men falling to rise no more, or in the agonies of death; hand-to-hand encounters; the varied emotions displayed in the faces of the combatants—these form some of the items witnessed in war photographs, and they convey to the spectator ideas quite different from those induced by the examination of a painting or drawing of scenes of a similar character. Some of the war series of stereographs issued by Messrs. E. and H. T. Anthony and Co., in connection with the great struggle between the Northern and Southern American States, show more vividly than the pen of any special correspondent could express the horrors of war, as displayed by dead bodies lying in the trenches or on the field, some of them having portions of the head or face blown away, or being otherwise terribly mutilated from the bursting of the devastating and deadly shell.

The photographer who visits the field of battle runs a great risk, in consequence of his affording a special mark for any hostile belligerent who, out of something akin to a spirit of sheer wantonness, might "draw a bead" upon him. Conversing, some years ago, on this subject with Mr. Sparling, he informed us that he sometimes "fooled" the Russians (during the siege of Sebastopol) by displaying a make-believe camera a little above the wall of a trench and raising his cap upon a stick close beside it, although only a few inches above the line of visibility—a proceeding which invariably ensured their being almost immediately perforated with rifle bullets, a quick return of the compliment being paid by Mr. Sparling, who, as a matter of preference, spent much of his spare time in the trenches in efforts of strategy or skill against the Russian sharpshooters by means of his rifle.

SOCIETY OF ARTS.

On Monday evening last, the 4th instant, the second of a series of Cantor lectures was given by Mr. T. Bolas, F.C.S., at the Society of Arts, John-street, Adelphi, London, W.C., the subject being *Recent Improvements in Photo-Mechanical Printing*. The special department taken up was *Type Blocks from Line Drawings and Half-Tone Subjects.* Mr. B. F. Cobb, Vice-President of the Society of Arts, was in the chair.

After Mr. H. Trueman Wood had explained that the incandescent lights in the room had on the last meeting burned dimly, merely because it was necessary, for the sake of the arc light which the lecturer used, to run the engine at a slow speed and not because of any defect, the Chairman introduced the lecturer.

Type Blocks from Line Drawings and Half-Tone Subjects.

Mr. Bolas said that phototypography and photolithography were almost the same thing—by the latter the proof being pulled off a prepared surface direct, whilst by the other the surface of a piece of zinc or other metal was etched into relief. It was probable that for every one picture produced by either process at the period of his last series of lectures there were ten produced now.

The production of these blocks is very easy when the subject is a line one, but not by any means so when the picture is in half-tone. It might, however, be said that the problem was now solved. The basis of most transfers for line subjects was now, the lecturer said, as it had been before, a surface covered with gelatine and albumen sensitised with bichromate of potassium. He wished to illustrate the improvement brought about by the introduction of the velvet roller.

A piece of paper sensitised in the way described was exposed under a negative, and was inked over in the old manner with a fatty ink—that is to say, the whole surface was covered with a thin film of ink. The whole was then placed in warm water, when the gelatine which had not been acted upon by light swelled up and became repellent of the greasy ink, which was easily removed, none remaining except such as was over those parts which had been acted upon by light, and which, consequently, did not swell. This image was used to transfer on to a lithographic stone for lithographic working direct, or on to a zinc plate to be etched with acid.

With the velvet roller the process was quite different. Instead of the whole surface of the bichromated film being covered with ink the roller was passed gently over it several times, when the ink took on the exposed parts representing the lines at the end, and a beautifully delicate transfer was the result. A copy of the American *Patent Journal* was handed round to show examples of this kind of work.

At this stage the lecturer passed round a couple of prints to illustrate the influence which photography had had upon the art illustration of popular journals. One was an engraving in a London illustrated paper of 1851, and showed the conventional outlines of the wooden frames; the other was from *Harper's Magazine*, and showed a half-tone picture which was as like an idealised photograph as anything could be.

Glass had been used for blocks, being etched with hydrofluoric acid. It was said that there was less under-cutting in the case of glass than of metals. The fact was that photolithography had for long failed to make that progress which it might—not because there was anything wanting in the process, but because lithographic machinery had not been worked with very great success. To Messrs. Sprague and Co. was, in great measure, due the credit of having put photolithographic machinery on a commercial basis.

In any half-tone process it was necessary to get an image in lines, dots, or stipple. A stipple could be got, as was well known, on the gelatine direct, simply by the reticulation of a bichromated gelatine surface. This could be used as a transfer. This process had been worked by Herr Pretsch, in 1860, and he (Mr. Bolas) thought that some of the results obtained by him then had scarcely been surpassed. It was marvellous how the reticulations would at times follow the outlines of trellis work and suchlike.

Mr. Bolas warned his audience that in judging the merits of various works shown on the walls of the room it was most necessary to take into consideration the amount of care spent in the printing. Thus some of the roughest there might in reality exhibit the most merit, inasmuch as no great care had been bestowed on the printing.

The method of getting a transfer by the use of a network was mentioned, and it was remarked that Meisenbach had, amongst other things, claimed as a novelty the adoption of slight motion of this network during exposure.

In 1873 Mr. W. B. Woodbury patented a method of reducing his gelatine relief into stipple, which promised well.

The Ives process was then described and illustrated. A Woodbury relief was inked and was brought into contact with grained paper. By this means, where the image was high the pyramids forming the grain of the paper were depressed, and a large dot resulted. Where the image was low the tips of the pyramids were merely touched, and a very small dot was produced. The image thus got was used as a transfer, or, better, as a means of getting a negative in stipple. If a transfer were taken direct the small spots were liable to spread out to some extent and to give a blurred effect.

Zuccato's process was then explained. A block of type metal is planed in very fine grooves. The block is now inked, a piece of paper is placed behind it, and behind that is placed the Woodbury relief. Pressure flattened the ridges of the type metal to different degrees and produced lines of different widths. A beautifully-defined transfer was thus obtained.

Messrs. Brown, Barnes, and Bell had made many claims in a recent patent for photo-mechanical methods, but none of them appeared to be very definite.

EDINBURGH PHOTOGRAPHIC CLUB.

Taking advantage of the presence in Edinburgh of Mr. A. L. Henderson, of London, that gentleman was entertained at dinner on Friday, the 25th ult., at Young's Hotel, Cockburn-street, by the Edinburgh Photographic Club. About forty gentlemen sat down to dinner, and nearly all the members of the Club were present. The chair was taken by Mr. J. G. Tunny, who had on his right Mr. Henderson, the guest of the evening. Dr. Thomson, R.N., was croupier. Among those present were Mr. W. Neilson, President of the Edinburgh Photographic Society; Mr. W. T. Bashford, Honorary Secretary of the same Society; Mr. Henderson, Perth, and others. After the usual loyal and patriotic toasts had been drunk,

The Chairman gave the toast of the evening, "Our guest, Mr. Henderson." He (the Chairman) said that it required no words from him to say what Mr. Henderson had done for photography. The name had been long prominently before them, as one of the leading men in the photographic world of London, and what he had done was well known to them all. He had been for a very long time one of his intimate personal friends, and his success in life was, he thought, well merited. It was to that success they were met to do honour that evening. The Chairman concluded with wishing long life and prosperity to Mr. Henderson.

It is needless to say the toast was drunk in a very enthusiastic manner.

Mr. A. L. Henderson expressed the pleasure he felt at meeting so many members of the Club and other friends. He said that on his first visit to Edinburgh, about forty-five years ago, "he had neither a shirt on his back nor a shilling in his pocket," he being born in Edinburgh about that time. Shortly after he was removed to Lasswade, six miles south from Edinburgh, where he received his education at the parish school. When of suitable age he went to assist a dispensing chemist in Frederick-street, Edinburgh, who made false teeth. He (Mr. Henderson) gave an amusing account of how he discovered the secret of the composition used in the manufacture of these. He stated that his interest was at the time drawn to photography by seeing in a photographer's window in Princes-street a daguerreotype view of the Castle Rock. The view was reversed in this picture, the Castle being on the right hand instead of the left, as it should have been. He was also so accustomed to examine the photographs in the window of Mr. Tunny's studio at Newington that he was afraid he had given a permanent flattening to his nose by the persistency with which he had gazed at these. After being for a time assistant to a chemist in Musselburgh he went to London. He related how he had sufficient to purchase his first camera and lens, and how, by gradual steps, he had attained a position in London. He further mentioned that it was while visiting the great Exhibition, in company with Mr. J. Traill Taylor, that he first saw some ceramic photographs, and when examining them he told Mr. Taylor that he thought he could produce better work. In a fortnight afterwards he had produced work which, it was thought, not only equalled, but excelled, that in the Exhibition. He (Mr. Henderson) in conclusion advised all photographers, above everything, to acquire a good knowledge of chemistry. He thanked the Photographic Club very warmly for the honour they had done him, and said it was a meeting he would never forget as long as he lived.

Mr. Neilson next proposed "Prosperity to the Photographic Club." He said it was barely necessary for him to propose this toast, as the Club was bound to be a success, the members of which it was composed being the picked men of the Edinburgh Photographic Society. The pictures they produced and exhibited yearly showed that in the photographic art they were second to none.

Mr. William Dougall then sang the following song, which, as containing a special allusion to Mr. Henderson, was enthusiastically encored:—

"OUR PHOTOGRAPHIC CLUB."

Tune: "The Bonnie Briar Bush."

In art and science every one
  Should interchange his views,
For thus fresh thoughts are oft begun;
  And progress then ensues.
It's good for men of every grade
  With kindred minds to rub;
A fair example we have made
  Our Photographic Club.

Our business meetings still display
  The talents each has got;
Discussion surely paves the way
  To elevate the lot.
Our greater minds will never try
  The lesser lights to snub,
Thus every one must profit by
  Our Photographic Club.

And here tonight, our yearly feast
  Has charms of light and shade,
It is a means, to say the least,
  By which good friends are made.
Then let us drink, with hearty cheers
  (Since we've enjoyed our grub),
Success attend in future years
  Our Photographic Club.

But we have here a special guest—
  Friend Henderson I name—
Who towers high above the rest,
  Enamelled into fame.
Old Rachel's skill he has outshone,
  And left her in the dub.
Long may he kindly look upon
  Our Photographic Club.

W. D.

Mr. Norman Macbeth, R.S.A., in responding to the toast, said no one could over-estimate the advantages accruing to the members of the Club by the way in which practical matters connected with photography were treated and discussed at their meetings. In a society such as the Edinburgh Photographic Society, which numbered over 400 members, it was scarcely possible to get those present at the meetings to take such an interest in the discussions as could be done when the members were limited in number, as they were to thirty members in the Photographic Club. The Club was more like a family party, where every one was expected to contribute his views on the subject brought before them for the evening.

Mr. Henderson, of Perth, next gave the toast of "The Edinburgh Photographic Society," which was replied to by Mr. Neilson.

The other toasts of the evening were "Kindred Associations," by Mr. Dougall, replied to by Mr. Brebner; "Photographic Literature," by Mr. Forgan, replied to by Mr. Bashford; "Professional Photographers," by Mr. Stewart, replied to by Mr. McKean; "Amateurs," by Mr. Brooke, replied to by Dr. Steuart; "Trade Interests," by Mr. Crighton, replied to by Mr. Turnbull. The toast of "The Ladies" was given by Mr. McKechnie, and replied to by Mr. Frank Moffatt.

The Chairman said that as the evening on which they met was the anniversary of the birth of Robert Burns, it would not be seemly that they should part without remembering that event—a circumstance which, as Scotchmen, they never could and never would forget. He proposed "The Memory of Burns."

After the health of the croupier had been drunk,

Dr. Thomson proposed the health of the Chairman, Mr. Tunny, whom he characterised as the "father of Edinburgh photographers."

During the evening numerous songs were sung by those present. Among those who thus contributed to the pleasure of the evening may be mentioned, Mr. Smith, Mr. Reid (who sang "My Heather Hills" with much feeling), Mr. Dougall, Mr. Brodie, Mr. Wardale, Mr. Crooke, and Mr. Henderson (Perth), who sang "The Great Hielan' Bagpipe, the Pride o' the Land."

As the time for separating had come, three cheers were given for Mrs. A. L. Henderson, and the company dispersed "A wee short hour before the twal'," after spending a very pleasant and happy evening.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on the 31st ult., the chair was occupied by Mr. F. W. Hart.

Mr. A. Cowan exhibited a lantern for dark-room use, constructed on principles similar to those involved in the present lighting of his dark room, as described at the last meeting of the Society. The front of the lantern was sixteen inches high by twelve inches wide, and was fitted with a sheet of green glass, and several thicknesses of yellow paper of the colours used by Mr. Debenham. There was also a sheet of plain glass to keep the papers flat between it and the green glass. The curved back of the lantern was lined with yellow paper. There was an ordinary fish-tail gas burner in the centre of the lantern, and a small metal screen in front of the jet just large enough to prevent the direct rays of light from the flame striking upon the front of the lantern. The lights in the room were turned down, and the jet in the lantern was lighted to show the members the amount and quality of the light. For freedom from chemical effect it was the safest light that Mr. Cowan had employed.

A Member inquired what was the object of the green glass in addition to the yellow paper.

Mr. Cowan remarked that Mr. Debenham had better answer that question.

Mr. W. E. Debenham said that when a considerable thickness of yellow medium was employed the colour transmitted became orange-coloured or even nearly red. A solution of bichromate of potash in a thin layer appeared of a pure yellow colour, but seemed changed in character as the layer became thicker. Green glass removed the orange or red effect which was painful to the eye, and cut off certain actinic rays which would pass without it. At the same time it cut off very little of the luminosity. To illustrate this point the glass was so placed as to cover one-half only of the lantern front.

The opinion of the members being asked as to the comparative amount of light for working passed through the two portions; the replies elicited were to the effect that the addition of the green glass screen caused very little lowering of illuminating power. Some of the members could see none at all, whilst Mr. Cowan stated that the green cut off a considerable amount of actinic power.

Mr. J. B. B. Wellington showed some negatives produced on plates coated with the slow bromide emulsion that had been described the previous week as prepared for printing lantern transparencies for lantern slides. There was some halation in the lights, which rather surprised him, as the emulsion was of a ruby colour.

Mr. A. L. Henderson observed that it was now found that ruby lets actinic light through.

Mr. Wellington also showed some more transparencies printed upon the same emulsion, some of them being of very warm tone. He had found it advantageous to employ the ferrous-oxalate solution made with eight parts of the oxalate to one of the iron, instead of the usual proportions of three or four to one. The restraining bromide had been employed in the proportion of twenty grains to the ounce of developer; and the exposure had been three minutes at a distance of two feet six inches from an ordinary fish-tail gas burner. He found that he had coated two hundred glasses of lantern slide size with emulsion prepared with one hundred grains of silver nitrate. An enlargement on opal glass was also shown. The opal had been coated with the same emulsion, which was poured off as closely as possible, so as to leave only a very thin film, which, however, was sufficient.

Mr. HENDERSON, who had recently returned from Scotland, said that he thought Mr. Jamieson, of Edinburgh, was on the right track for a dark-room light. He was not at liberty to give full details, but would say that Mr. Jamieson produced a complementary colour by rotation, and this colour was thrown upon a non-actinic screen. He (Mr. Henderson) then showed a developing dish recently introduced by the firm of Messrs. George Mason and Co., of Glasgow. The sides of the dish were of wood and the bottom of glass, and there was a covered space at one end forming a well. The novelty consisted in a string lying across the dish for the purpose of keeping the plate from sticking to the bottom, and for lifting. The string passed through two small eyelets, one at each side, and knobs prevented it from slipping through these eyelets. On pulling the string on either side the plate was lifted from the solution.

Mr. W. M. ASHMAN thought that fine binding wire would be better than string, as it would last longer.

Mr. HENDERSON did not think that binding wire would do at all.

The CHAIRMAN showed a developing-dish made of celluloid. On the bottom were two ridges to prevent adhesion of the plate.

Mr. A. HADDON called attention to an inaccuracy in an article in THE BRITISH JOURNAL OF PHOTOGRAPHY, page 51, on *English and French Weights and Measures*, in which two formulæ were given for converting degrees on Fahrenheit's scale into those of the centigrade.*

Mr. C. B. Cutchey's resignation as secretary was read, and Mr. J. J. Briginshaw appointed to be Secretary of the Association.

It was mentioned that Mr. Hart's lecturette on *Residues* would be delivered on Thursday next, the 14th instant.

THE POSTAL PHOTOGRAPHICAL SOCIETY.

A COMMITTEE meeting of this Society was held on Wednesday last, the 6th inst. After the minutes of the previous meeting had been read and confirmed, the following candidates—each of whom had submitted specimens of his work and declared himself a *bonâ fide* amateur—were elected members:—H. G. M. Conybeare, Ingatestone; A. Suzanne, Woburn; Rev. A. M. Macdona, Folkestone; Rev. H. Victor Macdona, Cheadle Hulme; Rev. J. Carter Browne, D.D., Manchester; Rev. Locke Macdona, Cheadle; John Holloway, Folkestone; Rev. H. Von E. Scott, St. Leonard's; H. E. Lees, Manchester; T. Mansell, Bristol; Harold Sands, Nottingham; and F. Pardoe, Aberdare.

An application for membership was read from a French gentleman, but the Hon. Secretary was instructed to inform him that the rules would not permit of the Society's albums or collections of competition prints being sent abroad.

A letter was then read from Mr. G. Bankart, suggesting that a uniform size and thickness of mount should be adopted for future competitions for all pictures, large or small.

The HON. SECRETARY said that this would be a very great advantage, and would enable the competitions to be sent round, as the first one was, between boards. It was the small mounts which necessitated a box, by preventing a flat package being made, and by moving about they caused friction, to the destruction of the other prints. It was, therefore, resolved that for the future—"All pictures, *of whatever size*, intended for competition be excluded unless mounted on cards of the uniform size, 15 × 12 inches, and uniform thickness 4-sheet." This was a trade size, and the Hon. Secretary had seen Messrs. Woolley and Co., 210, High Holborn, who would supply boards of this size, quality "fine," in twenty-three tints besides white, at 12s. 6d. per gross, or by the dozen.

The thanks of the Society were ordered to be conveyed to Mr. Bankart, and members were recommended to obtain samples, as it was thought this selection of tints would suit all tastes.

The thanks of the Society were ordered to be sent to the Editor of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for a copy of the 1884 edition, and to the Editor of the *Photographic News* for a copy of the *Year-Book*.

Competition No. 3, which had completed its first round, was then examined. Mr. Baylis had acted as scrutineer of the votes, and announced the numbers as follows:—

Class I. Landscape between 5×4 to 10×8.—First prize, H. H. Cunningham, 58 votes; second prize, G. Bankart, 50 votes.

Class II. Portrait of Member taken by Himself.—Prize, W. Adcock.

Class III. Architectural Subject.—First prize, F. Gorham Ticehurst, 65 votes; second prize, G. Bankart, 52 votes.

In Class II. the votes were—G. Bankart 67 votes, W. Adcock 37 votes; but the committee disqualified Mr. Bankart's exhibit, as he has not complied with the rules by giving full particulars on the back of the mount. They also disqualified Mr. Adcock's picture marked "A," as it had competed before in competition No. 2. Mr. Adcock, therefore, gained the prize for votes given in respect of his other exhibits in that class.

Dr. DAY moved that in each album a prize be given for the best picture, in order to raise the quality of the prints in the album. Each member to have one vote simply for the best picture. The prize to take the form of an enlargement in carbon from the negative.

It was pointed out by the HON. TREASURER that the question of funds was the only drawback to this, and it was resolved that so long as they permitted it this course should be adopted. The pictures were to be placed in the albums as nearly as possible in the order in which they came to hand, and members were requested to date their noting forms, as an assistance to the mounter.

Mr. J. W. LEIGH had made a report to the Society upon samples sent it of Schölzig's albumenised paper, and on Seorah's canary medium. It was ordered that he should be thanked on behalf of the Society.

* See note in leader columns.—EDS.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

THE annual general meeting of this Association was held at the Society's office on Wednesday, the 30th ult.—W. S. Bird, Esq., presiding. The minutes of the previous meeting having been read and confirmed, Messrs. E. G. Gauly, F. T. Beeson, and W. H. Penn were elected members of the Association.

The SECRETARY then submitted his report, with balance sheet and summary of proceedings of the Society since its foundation, as follows:—

SECRETARY'S REPORT.

IN submitting my report of the business done by the Association during the past year, I desire to call attention to the fact that, although the total receipts are not equal to those of 1882, the position of the Society is really improved—a considerable increase of members having been enrolled during the last few months, and the funds of the Association having increased from £139 18s. 1d. to £159 9s. 8d., being a clear gain of £19 11s. 7d. during the year.

Receipts.—The honorary members have contributed £24 3s. 6d., the ordinary members £17 5s., and the proceeds from the evening at the Exhibition of the Photographic Society of Great Britain £6 6s. 7d., making a total of £47 15s. 1d. The difference between the receipts for 1882 and 1883 (£10 0s. 11d.) are accounted for by the fact that in the former year several gentlemen combined to hold a *soirée* and ball, which realised £9 16s. 6d. in aid of the funds. It is to be regretted that the experiment was not repeated in 1883. Further: the proceeds from the Exhibition are £3 19s. 5d. below those of last year; it will, therefore, be seen that the reduction in the income of the Association has not arisen from a decrease in honorary and ordinary members' subscription, which combined are £3 15s. in excess of this source of revenue in 1882.

Expenditure.—The assistance given has been of very moderate amount. Non-members still continue to apply for assistance, and if the rules allowed such applications to be entertained the funds of the Association would be rapidly reduced. The plea generally given in reply to the query as to why applicants had not joined the Association has been—"Oh! I did not know of its existence." It is a matter of surprise how they found it out when its help was required. The working expenses have been £22 3s. 6d., or £1 16s. 3d. less than last year.

Balance Sheet for Year ending December 31st, 1883.

REPORT OF THE BOARD OF MANAGEMENT.

IT is again the duty of the Board to submit its annual statement to the subscribers to and members of the Association, and to add a few words to the information as to the proceedings of the year contained in the Secretary's report given above.

The facts this year are less encouraging than in the previous one. There has been a welcome increase in the receipts from honorary sources through the generous contribution of E. Horner, Esq., but the receipts from ordinary members exhibit a slight decrease. Considering the length of time the Association has been in existence, the amount of publicity liberally afforded by the photographic press, and the advantages derived from the annual benefit night at the exhibitions of the Photographic Society of Great Britain, your Board cannot but feel that the progress made towards the realisation of its aims is but slow. At present the great majority of the photographic profession, both masters and men, are practically indifferent, and the members must take account of this fact. It behoves them to consider whence arises this apathy, and what means can be taken to remove it.

The organisation of the Association is arranged on an extremely economical scale, and it appears to the Board that nothing further can be done in this direction if any administration is to be maintained. With a very trifling extra outlay ten times the present work of the Association can be carried on, in which case the proportion of the expenditure to effective results would compare favourably with any benevolent organisation extant.

The foundations of a Photographers' Benevolent Association has been laid. There is an accumulated fund of about £160, and an effective administration; but for a real success the hearty co-operation of the members of the photographic profession is absolutely essential.

Not long after photography merged into a permanent industry it became evident that a fund of some kind was needed to assist those of its workers who were overtaken by misfortune in their new avocation, and columns of the journals were from time to time filled with suggestions as to the best mode of dealing with the difficulty. Time rolled on, a special plea being occasionally made on behalf of some fallen brother, but nothing was done until a few gentlemen more determined than the rest made an effort, in 1872, to establish an Association worthy of the profession to which they belonged. For many months the labour of organising was carried on by the promoters, who in 1873 called a public meeting of professional photographers to discuss the various schemes suggested. At that gathering was formed the nucleus of the Photographers' Benevolent Association, whose funds have slowly but steadily augmented. The Association has been instrumental in obtaining employment for many of its members, has furnished means to enable them to proceed to the provinces when required, and has rendered material pecuniary assistance to many whom adverse circumstances have placed in the position to need it.

Its power of doing good is necessarily limited by the resources at its disposal. It has now entered the tenth year of its existenae, and may perhaps claim to merit the larger support it needs for effective working. The Board now puts before its members and before the profession it desires to serve the facts of the case, and it rests entirely with the profession if the Photographers' Benevolent Association shall become a useful and flourishing institution to dispense a kindly help to members who may fall wounded in the ranks, or that it shall be denied the fruition of its good intent.

Both reports were adopted.

The Chairman then said the report had placed before its members the position of the Association, and stated that the Board, which consisted of the faithful few, would be glad to receive co-operation, and asked for suggestions which would tend to increased interest in the Association.

Mr. W. M. Ashman said the rule making two classes of members appeared to be a mistake, and to his knowledge deterred some of the profession from supporting the Association. There was no objection to receiving donations from anyone and to any amount; but why an annual subscriber of one guinea should not participate equally with the half-guinea subscriber seemed a puzzle to many. He would suggest altering the rule. Another matter was the amount of subscription. Why not reduce it to 5s.? Masters and men would gladly pay that amount who now withhold a guinea or half-guinea. When employers became regular subscribers they will have no hesitation in referring needy cases to the funds. He should like to know the views of the members generally on these suggestions.

Mr. H. J. Thorne considered the rule admitting two classes of members was one which needed altering. He was not prepared to go so far as the previous speaker and reduce the subscription.

Considerable discussion took place in which the Chairman, Mr. Rolph, and others joined. The feeling of the meeting was strongly in favour of one kind of subscription only—membership, in fact, to be on the payment of ten shillings and sixpence annually. It was felt, first, that the justice of the case demanded that every member should be entitled to the benefits of the Association; and, secondly, that many gentlemen would, in addition to the fee of membership, give a further subscription or donation. It was resolved that steps should be taken to alter the rule.

The Association having sustained a loss during the year of two officers—J. H. Dallmeyer, Esq., one of the Vice-Presidents, of whose benevolence the Society has had testimony, and C. G. Collins, Esq., a good working member of the Board—the meeting desired to express their sympathy with the relatives of these gentlemen.

The following are the officers for the ensuing year:—*Vice-President:* Rev. F. F. Statham, M.A., F.G.S.—*Trustees:* Col. Stuart Wortley and Capt. W. de W. Abney, R.E., F.R.S., F.C.S.—*Treasurer:* H. Baden Pritchard, Esq.—*Auditors:* G. Taylor, Esq., and J. S. Rolph, Esq.—*Board of Management:* W. S. Bird, Esq., Chairman; H. J. Thorne, Esq., Deputy-Chairman; Messrs. W. M. Ashman, H. J. Burton, T. Bolas, A. J. Brown, F. H. Berry, E. G. Gandy, J. A. B. Hall, A. E. Hyde, F. J. Mitchell, J. S. Rolph, S. Saunders, and R. E. Wilkinson.—*Secretary:* H. Harland.

The meeting terminated with a hearty vote of thanks to the Chairman.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

The seventh general meeting of the session was held in the Religious Institution Rooms, on Thursday, the 24th ultimo,—Councillor Robertson in the chair.

Mr. A. L. Henderson, of London, and Mr. J. G. Tunny, of Edinburgh, were introduced to the meeting. The minutes of the previous meeting having been read and approved of, the question-box was opened and found to contain the question—"What is the best method of enamelling silver prints?

Mr. Urie said the process was exceedingly simple. A glass plate is cleaned, rubbed with French chalk, and coated with collodion. When dry the collodion is coated with a thin varnish of gum dammar in benzole, to prevent the gelatine mountant permeating the collodion. The print is then mounted down on the plate with gelatine; a thin sheet of paper is mounted on the back of the print with the same medium, and when dry it is stripped from the glass.

Some discussion then took place as to the advisability of using varnish on the collodion, the arguments for and against being about equal.

Mr. A. L. Henderson thought enamelling photographs was a mistake altogether. In his experience they faded considerably quicker than plain albumenised prints. He thought the addition of the benzole varnish to the collodion was a decided improvement.

Mr. Blaikley showed a circular camera constructed almost on the principle of a round collar-box. The lid (on which the focussing-screen and slides work) revolves on the body of the box, so that either an upright or oblong picture can be taken without changing the camera. This lid is prevented from coming off by means of four pins working in a groove cut round the box. The front part of the camera is, as it were, the bottom of the box cut out. To this one end of the bellows is attached, the other to the inside edge of the box next the lid. The bellows is made octagonal, but the ends readily accommodate themselves to the circular form. The tailboard is simply a flat rod (about one inch broad and three-eighths of an inch thick) cut in two, and each half hinged to the triangular top of the tripod, so as to fold down against the stand when not in use. When in use they are kept in position by a binding screw and small plate with socket. The focussing arrangement consists of a rack and pinion, the rack being inserted along the bottom of the rod. The focussing-screen is not hinged, but slides in the same groove as the dark slide, and is prevented by a check from coming out entirely. A small spring is fixed between the box and lid, so as to snap and retain it in an upright or oblong position. The wood is plane tree ebonised, and, being all turned, the cost is very little.

Mr. McGhie exhibited several pieces of apparatus, including a camera, which was much admired; also a drying-box $21 \times 12 \times 12$ inches, capable of holding six dozen quarter-plates, the ledges on which the plates rest (face downward) being bevelled. The ventilators at top and bottom have dust cheeks, and a continuous stream of cold air is caused to pass over the surface of the plates, which dry in from six to eight hours. He further showed a dry-plate lantern with three distinct forms of light—ruby light with a shade for the eyes; clear light for making tranaparencies; and opal glass for examining developed plates. He also exhibited a studio shutter, the flap of which was divided into two parts, and opened sideways by pneumatic arrangement.

Mr. Lorn Campbell exhibited a picture of a transformation scene in a pantomime. It was exceedingly sharp and well-defined in every part.

The Secretary showed the result of experiments he had made with some extra-rapid, ready-sensitised paper which he had received from Mr. Otto Schölzig. The experiments proved the paper slightly more sensitive than ordinary paper, but more difficult to tone.

The Chairman then called upon Mr. J. Y. McLellan to introduce a discussion on *The Cause of Fading in Silver Prints.*

Mr. McLellan commenced by pointing out the importance of a knowledge of the subject from a general as well as a photographic point of view. We could not (he said) look over our own or friends' albums without being made painfully aware of the fact that many of the so-called old-fashioned photographs were rapidly fading away. This was all the more to be regretted since old photographs were often the only remaining portraits of departed friends, and their value consequently increased with years. He remarked that, in his opinion, there were two kinds of fading—one which might occur at an early stage in the life-history of the photograph, and which could generally be attributed to faulty manipulation on the part of the operator; but the more important form was that which took place after many years, and which could not be accounted for in this way. He had given the matter a good deal of consideration, and had come to the conclusion that the cause of this insidious form of fading was entirely due to atmospheric influence. He said that some years ago he was interested in a chemical investigation, undertaken to discover the cause of decay in the leather bindings of the books in a gentleman's library. These books were submitted to analysis and found to contain considerable quantities of sulphuric acid, and the only legitimate explanation of this seemed to be that the sulphur compounds in the gas on burning were converted into sulphurous acid, which was absorbed by the books, and ultimately became oxidised into sulphuric acid, and so accounting for the corrosion of the book bindings. He said that, in his opinion, this was also the explanation of the fading of photographs after keeping for many years. In order to put it to the test an old faded photograph, which had hung upon the walls for about fifteen years, was torn into pieces and immersed in water. This became strongly acid on testing with litmus paper, and on the addition of barium chloride gave a dense white precipitate of sulphate of barium, proving the presence of a large quantity of sulphuric acid. The water also decolorised permanganate of potash, which suggested the presence of some reducing agent. He said that his experiments up to the present were merely preliminary tests. He hoped soon to go into the subject quantitatively, and strongly recommended this to the members as an important subject for investigation.

An interesting discussion followed, and, several members having intimated their intention to investigate the subject experimentally,

The Chairman proposed that the discussion should be continued at the next ordinary meeting on the 21st of February, and it was arranged that Mr. A. Duthie should read a paper on the subject that evening.

Mr. A. L. Henderson was elected an honorary member, and Mr. George McKenzie, of Paisley, was elected an ordinary member, of the Association.

The meeting then closed with votes of thanks to the exhibitors of apparatus, to Mr. McLellan, and to the Chairman.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The ordinary meeting of this Society was held at the Free Library, on Thursday, the 31st ult.,—Mr. B. Boothroyd, President, in the chair.

The minutes of the annual meeting having been read and confirmed, the Chairman, after a few graceful valedictory remarks, vacated his post, and Dr. Kenyon, the President for 1884, took the chair.

Messrs. Cockbain, Irvin, Kerry, Morris, Parkyn, Robinson, Smith, and Watts were elected members of the Association.

The Hon. Secretary read a letter from Mr. Frank Leslie, the chairman of the Executive Committee of the Associated *Soirée*. The consideration of this, on the motion of the Rev. T. B. Banner, seconded by Mr. J. A. Forrest, was deferred till next meeting.

Dr. Kenyon then delivered the following—

Inaugural Address.

In the first place, I must express my sincere thanks for the great honour you have done me by electing me your President, and I must ask your kind indulgence and assistance in fulfilling the corresponding duties.

On such an occasion as this it is convenient to take a general survey of things, and not considered unpardonable to indulge in reminiscences.

Looking at our doings from outside, we find ourselves as photographers engaged in one of the most wonderful of all the wonder-working processes of this eventful age. The dream of the necromancer of the middle ages is wellnigh fulfilled by us every day. If we cannot actually transmute the baser metals to gold we can transmute inert and sordid matter into the pure gold of ethereal beauty. We can bring to light the secrets of the invisible changes of the minutest molecules. We can seize with a rapidity which would satisfy the recording angel the fleeting actions of time. We resemble those ancient sorcerers in less agreeable ways. Like theirs, our proceedings are not very highly esteemed by the common herd. Fortunately we receive more compassion than blows; but the fact remains that we are not always so highly appreciated as we could wish. Witness Captain Abney's story of the Spanish peasant who gave him a halfpenny.

Although, unfortunately, not a very old member of this Society, my experience of photography reaches somewhat far back, and, being in itself in some degree an epitome of the history of the science, it may not be uninteresting if I give a short account of it. I would not, however, venture to trouble you with anything so personal, only it may remind some of you of similar experiences, and it may serve to illustrate the contrast between the multitudinous facilities which we enjoy here and now, compared with those obtained in a country village twenty-five years ago.

It is curious to trace the first dawnings of things photographic on the mind, so let me first carry you back to a period still earlier than that which I have named. When a child under six years of age I was taken into a show at a fair. It was a large *camera obscura*, and I can well remember the wonder with which I saw spread out on a table the image of the surrounding buildings, the richness of the colouring, and, most astonishing of all, the moving images of the people walking outside. My mind often recurred to the subject, and I tried in vain to conceive how it might be effected. Notwithstanding this experience, when later I saw a photographer at work I thought the affair was a trick.

Next, at school, playing with a lens, some of us noticed traces of an image, and on partially darkening the window were delighted with its beauty. With this fresh in my mind, school days over, I fell in with some articles by Sir David Brewster in an art journal, in which the photographic efficiency of the simple spectacle lens and the principles of the stereoscope were enunciated. At the same time some even then old magazines came to hand, giving an account of "photogenic drawing," as it was at first called. Putting together the ideas thus suggested, I began to experiment with nitrate of silver and common salt on writing paper, and also with bichromate of potash on paper. Soon a camera was constructed of pasteboard and fitted with spectacle lenses. Not even a sky outline being obtained with the foregoing chemicals, the calotype process was attempted; but this proved a failure, as might be expected, considering that in the early formula a dose of the developing solution was applied before exposure.

Next I fell in with a pamphlet, by Mr. William Crookes, on the waxed-paper process. This led to better results. Then I made the acquaintance of an enthusiastic amateur, who lent me The British Journal of Photography, and about the same time a friend gave me a copy of Hardwich's *Photographic Chemistry*. By this time, with some reluctance, the spectacle lenses had been sacrificed in favour of a good quarter-plate landscape lens by Jamin (à Paris), kindly presented to me by my father. Thenceforward progress was easy. An article in the Journal recommended a process in which turpentine was employed as a solvent for the wax and iodine. This proved a great success.

The village carpenter was now taken into confidence, and between us we constructed a very light, strong, and effective stereoscopic camera. A 5 × 4 camera was also extemporised out of a deal box. Printing-frames were, of course, easily made, pressure being obtained with india-rubber, screws, or wedges. The stand was a difficulty, but a cheap one just came out in time for me.

Objecting to the grain of paper I proceeded to experiment with glass. First I tried albumen, but this proved very awkward to manage on account of the difficulty of getting an even coating and drying free from dust. Albumen on collodionised glass, recently referred to in the Journal as the best means of making transparencies, I found easy to manipulate, but very slow. I have, however, preserved one fragment of a negative as a microscopic object, showing wonderful definition in a distant signboard and placards of a post-office window. Wet collodion was then taken up, and was, of course, a great advance; but, wishing for something portable, I succeeded very well with Fothergill plates. Dr. Hill Norris's plates gave very beautiful results, but did not always prove so reliable as the Fothergill.

From 1863 to 1878—Rip Van Winkle-like, as regards photography—I fell asleep; but when I awoke I found wet collodion still the photographer's sheet anchor, and the dry plate that was to eclipse it in rapidity still a dream—very quickly to be realised. I found, however, a startling development of collodion in the collodion emulsion processes, which I received just in time to try before they also lapsed into the limbo of forgetfulness. Then came Mr. Charles Bennett's wonderfully-lucid exposition of the principles which have worked the revolution in favour of gelatino-bromide, the success of which is the cause of our large accession in numbers. And here I am in duty bound to remind some and inform others that the collodion emulsion processes had their birth in this Society, and that we number amongst us one famous for his long devotion to gelatine.

With your permission I will now say a few words about a rival attraction which is absorbing much attention, and which is not altogether a rival either, but has special claims upon us as photographers. The development of the tricycle during the last two or three years is comparable with the rise and progress of gelatino-bromide, and like it has created a new industry of even national importance. There is a closer affinity between cycling and photography than is at first sight apparent. To paraphrase a familar saying: much though I love photography—great as is the charm of devising and accumulating apparatus and of working the varying and multitudinous processes—I love the objects I wish to photograph even more—the mountains and rocks, the landscapes, the sea, the clouds, objects of architectural interest, and the countenances of one's friends. It is because these are so dear that photography is most beloved as a means of securing a closer communion. And what, I should like to know, more deeply engraves upon one's soul the features of a delightful country than riding through it on a tricycle? The very exertion—nay, toil—of the journey ensures an acute remembrance of its details; and what more promotes good fellowship than the freemasonry of the wheel? As in photography, there is scope for exertion, inasmuch as there is a heavy weight to be carried about, and there is a delicate machinery to be cherished with almost human affection. As in the pursuit of photography, diversified scenery is brought into view. There is abundant scope for ingenuity and invention, both in mechanism and field of operations. What is more to the point: in the tricycle we have a most useful means of transporting photographic apparatus. In the autumn of 1879 I took with me on a "Salvo" tricycle through the heart of Wales a 7 × 5 camera, stand and plates, along with a knapsack, weighing altogether some thirty pounds. On my "Humber" tricycle (a fifty-two inch) I can comfortably carry a Rouch's 12 × 10 camera and half-a-dozen plates, with stand. As many of the cycling clubs are forming photographic divisions, it might be worth while for us to think of forming a cycling division.

Passing on to consider the progress made during the past year in the practical working of photography; we have to notice that in the gelatino-chloride process one source of weakness seems to have been effectually removed—a source of weakness due to the very perfection of gelatino-bromide in regard to sensitiveness. In gelatino-chloride we have the means apparently of doing with gelatine what hitherto has still to be looked for elsewhere, namely, the perfection of transparencies, whether for lantern purposes, enlargements, or reproduction of negatives. I hope, in direct printing on gelatino-chloride plates, many of us will find greater ease, certainty, and economy than in the development process. And I venture to hope that, through gelatino-chloride emulsion, we may come to a perfect paper process—one which will give the perfection of a glass transparency on paper, free from the loss of detail and finish sustained in the toning and fixing of ordinary paper prints. This, it occurs to me, might surely be attained by some such process as by coating Messrs. Goodall and Steven's enamel paper with gelatino-chloride.

The magnificent enlargements, exhibited by Professor Donkin, of Swiss mountain peaks, are a great encouragement for those who look to obtaining from small plates enlarged negatives equal to large pictures taken direct; and here, again, I would suggest that gelatino-chloride will come in useful, for a brilliant transparency may by this process be obtained from a negative otherwise unfit for enlargement.

There is still much room for improvement in cameras, but serious efforts are being made to supply the want. This, I submit, will only be satisfied with an automatic arrangement for exposing plates or films carried *en masse*: and I would suggest that a great step would be secured if the sliding shutter of the dark slide were replaced by a hinged shutter opening entirely within the camera. This might easily be done.

In the working of the gelatino-bromide process valuable additions have been made to our resources in the introduction of the citrates, by Mr. G. Watmough Webster, as a means of obviating the results of over-exposure, and in the improved methods of silver intensification by Mr. William Brooks and Mr. B. J. Edwards. The use of the carbonate of soda developer appears to be gaining ground, and I have myself had very satisfactory experience of its usefulness.

A great improvement in the illumination of the dark room for development purposes is now obtained, and this seems likely to find its perfection in the use of a monochromatic light such as is announced from Paris to be obtainable by a mixture of spirit and perchlorate of soda burned in a spirit lamp. This is said to give an abundant yellow light free from actinic influence. For the illumination of dark interiors or portraiture by night, where a short exposure is desirable, we have had brought forward in the oxymagnesium light the very *acmé* of an inexpensive and portable device.

In this connection I may point out that for copying pictures and small objects, where a longer exposure is admissible, the lens of a graphoscope, for rendering parallel the rays of a paraffine lamp, answers admirably, whilst for making enlargements on gelatino-bromide paper from small negatives the same lens, used along with a smaller, shorter-focus, double-convex lens to act as a condenser, will be found effective with the same simple source of light, the precautions necessary being to place—1. The condenser at or about its focal distance from the lamp. 2. Place the graphoscope lens at or about its focal distance from the condenser. 3. Having placed the negative close to the graphoscope lens in the slide of the camera, to use for making the image a lens of longer focus than the graphoscope lens, and, if possible, of at least so large an aperture as that of rapid symmetrical type.

In conclusion: it only remains for me to wish you all and each a happy and prosperous New Year!

Mr. J. H. Day, the Librarian, announced donations to the library of two parts of the *Photographic Times*, and a translation, by Captain Abney, of a work by Dr. Eder on *Spectrum Analysis*, for which the hearty thanks of the members were accorded to the donors.

Mr. J. A. Forrest proposed, and Mr. J. H. Corkhill seconded, a vote of thanks to the President, officers, and judges of the past year.

Mr. W. H. Kirkby then, in accordance with his notice, proposed to alter Rule V. to—"Honorary members shall be nominated by the Council; but their election must be confirmed by the members of the Association present at one of the ordinary meetings; the election, both by the Council and at the meetings, to be by ballot, and to be carried by the majority of the votes. Honorary members shall retire at the next, and at every annual, meeting, but are eligible for re-election on the recommendation of the Council. Honorary members shall be entitled to attend meetings, but are not to receive the presentation print, and shall not serve on the Council or vote on any question whatever."

Mr. B. Boothroyd seconded the resolution.

Mr. J. H. Corkhill moved, as an amendment—"That the election of honorary members by ballot and their re-election annually shall not form part of Rule V."

Mr. J. A. Forrest seconded the amendment, and after some discussion the amendment obtained a majority of votes. On being put to the meeting by the Chairman as a substantive motion the amendment was carried.

The Chairman distributed certificates of honourable mention to the following gentlemen, whose pictures had gained prizes in the competition for 1883:—Messrs. Beer, Ellerbeck, Hall, Kirkby, and the Rev. H. J. Palmer.

Mr. J. H. T. Ellerbeck (Hon. Treasurer) spoke at some length on the financial position of the Association, pointing out that, owing to the large and rapid growth of the numbers of the members and the very large attendance at the monthly meetings, it would be necessary to economise the working expenditure considerably, since it would no longer be possible to give each member a presentation print of the cost of half his subscription, and provide him with tea at each of the meetings.

After some discussion it was decided to present each of the members entitled to it with an unmounted enlargement of the usual size.

Mr. Ellerbeck suggested that a list of dates and of places for the excursions of the year should be drawn up by the Secretary, and sent to the members, printed in the February circular.

The Hon. Secretary gave a report of the Society's exhibition at the Associated *Soirée*, gratefully acknowledging the labours of Messrs. Crowe, Forrest, and Guyton in co-operating with himself in the arrangement of the pictures.

He (the Hon. Secretary) also related his experiences at Sheffield on his recent visit to the Exhibition there, to which the Liverpool Amateur Photographic Association had contributed a large number of exhibits.

Mr. McKellen, of Manchester, exhibited and explained his new portable and ingenious camera, and received the cordial thanks of the meeting.

The Rev. H. J. Palmer wished to make special mention of the kindness of Professor Donkin in sending down for their enjoyment that evening his splendid transparencies of his views in the High Alps, and a hearty vote of thanks was proposed and carried unanimously.

Mr. J. Knott then showed Professor Donkin's pictures in the oxy-hydrogen lantern, and also a number of other slides contributed by Dr. Kenyon, Mr. Newhall, Rev. H. J. Palmer, Mr. A. Scott, and others.

Hearty votes of thanks were proposed and carried to Mr. Knott and Professor Donkin and the other exhibitors of slides.

Mr. A. W. Beer showed a new carrier for the lantern by Mr. McKean, of Edinburgh, for instantaneously changing the pictures on the screen. Its ingenious construction was much admired. Mr. Beer also exhibited a portable adjustable view-meter of fine make and finish, designed by himself and made for him by Mr. Crowe.

The Rev. H. J. Palmer exhibited some fine enlargements, by Morgan, on gelatino-bromide paper, of negatives taken by him at Chartres and in Switzerland.

The Council finally decided upon an enlargement of Mr. Palmer's *North Portal of Chartres* as the presentation print for 1883.

Some prints on a new doubly-albumenised sensitive paper, by Mr. Schölzig, of London, were to have been exhibited and discussed; but, owing to the pressure of business, these and other matters were postponed to the next meeting.

Correspondence.

February Meeting of the Photographic Society of France.—Presentation of Cameras.—Presentation of a Photographic Album from St. Petersburg.—A New Photographic Journal from Oporto.—M. Audra on Hyposulphite before Development.—M. Vidal's Presentation of a Pocket Camera.—Presentation by Professor Stebbing of a Packing Box for Dry Plates.—Communication by M. de la Noë on Actinometers.—Iodide of Silver a Powerful Antiseptic.—Modification of a Travelling Lantern.

The monthly meeting of the Photographic Society of France was held on Friday evening last, the 1st instant,—M. Peligot in the chair.

M. Fontaine presented two small cameras and a rapid shutter (guillotine form)—nothing new. Evidently the inventor or, at least, the person presenting the same was not *au courant* of the progress made in photographic joinery during the last few years.

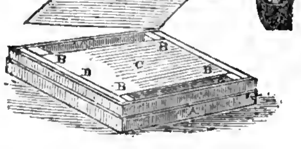
The Society received a magnificent present from Mr. Chapiro, of St. Petersburg, consisting of an album containing the collection of proofs in which a celebrated actor had personified a madman. These proofs were obtained in order to illustrate a Russian novel, entitled *Mémoires d'un fou*. On the blank side of the album, opposite the proof, is the sentence or passage of the novel which gave birth to or inspired the posture. This sentence is printed in the Russian and French languages. The preface, which was read, described how the idea of illustrating books by means of photography came into existence, and went on to say how deeply it is to be regretted that the gestures and positions of celebrated actors who have interpreted Shakspeare's plays—such as *Hamlet*—have not been handed down to posterity. The idea of illustrating books by means of instantaneous photography has opened a new field to the trade.

M. Carlos Relvas and his daughter, whose love of photographic manipulations has been so often spoken of, have undertaken to compile a monthly journal on photography. The first number was presented to the Society, but the pleasure it gave was diminished by the fact that few, if any, of the members were acquainted with the Portuguese language. The new publication was well received by all, bearing, as it does, the name of M. Carlos Relvas, which is a passport to all interested in the progress of photography. It may be remembered that this gentleman received, a short time ago, the decoration of the Cross of the Legion of Honour from the French Government, as a homage to his indefatigable perseverance and disinterested application to the progress of photography. The British Journal of Photography and its legion of correspondents will not be behindhand in wishing success to the *Arte Photographica*, and health and strength to its distinguished *collaborateurs*, Mademoiselle and M. Carlos Relvas.

M. Audra made a very interesting communication on the advantage of plunging a gelatino-bromide plate into a weak solution of hyposulphite of soda before developing the latent image with ferrous oxalate. After the immersion in a solution of about one grain of hyposulphite of soda to about one quart of water the plate is well washed and developed. M. Audra exhibited some very fine negatives treated in this way. He says it is far preferable to putting hyposulphite of soda (as formerly proposed) into the developer.

M. Vidal, who, it may be remembered, made a very interesting communication (of which I gave an account in my last letter) on the ease and convenience of films for photographic excursions, their development, and other manipulations. This gentleman completed his communication by the presentation of a pocket camera made by himself, as no camera-maker would undertake to construct such a small instrument. A pocket camera indeed it was, taking up very little space, and with six double dark slides weighing only two or three ounces. No glass plates are used. M. Vidal informed the Society that the dark slides were furnished with Prof. Stebbing's new transparent films, which were very light and convenient for the purpose, and which preserved their flatness when the diachylon is employed to aid adhesion. The camera and dark slides were very much admired, and M. Vidal was highly felicitated on his new talent in cabinet work.

Prof. Stebbing submitted to the Society a new packing-box for dry plates, presented to him, during his last visit to England, by Mr. A. L. Henderson. This box is not unknown to the readers of The British Journal of Photography, having been brought to their notice by Mr. A. Cowan. It merits, nevertheless, a slight description. The box may be made of wood or eardboard. It is the exact length of the plates which it is intended to hold, but a quarter of an inch larger on each side. To keep the plates from shaking or moving four pieces of wood a-quarter of an inch square, and in length the height of the box, are glued firmly to the sides, about three-eighths of an inch from the ends of the box. These wooden pillars serve two purposes—first, to keep the plates, as was said before, from moving; secondly, to maintain narrow strips of paper, used to separate the plates one from the other, so that the sensitised surface should not come in contact with the back of the plate. This is attained in the following manner:—A piece of eardboard is cut into strips in length the width of the box, and about five-sixteenths of an inch wide. A plate is lowered down into the box, sensitive side upwards; two bands are now taken, one of which is dropped down between the pillars at one end, and the other between the two pillars at the opposite end. Another prepared plate is now put in, but this time with the sensitive surface downwards. Two more bands are introduced in the same manner, and another glass added, face downwards, and so on until the box is full. The cover is then adjusted, a band pasted round to keep out light, and the parcel is ready for the market. The box presented was examined with great interest and care by the members.



A, plate box. B B B B, wooden pillars. C, stock of prepared plates. D, band of paper separating plates. E, plate about to be put into box.

M. Guilleminot informed me that he had had a great number of such boxes made about a year ago.

The advantages as well as the faults of this box were duly discussed Whether the stains at the end of the plates caused by the paper wil counterbalance the great advantage which a photographer, and especially an amateur, must derive by being able in semi-darkness to take the plates out of the box and put them, by feeling only, into the dark slide, remains to be proved. As for stains: if pure paper or strips of pure gelatine be used instead of cardboard no trace of stain can be detected.

M. de la Noë communicated to the Society his observations and practical experiments with Mr. L. Warnerke's actinometer. This instrument is fully described in THE BRITISH JOURNAL OF PHOTOGRAPHY, 1880, page 53. It appears, as far as I could understand, that M. de la Noë obtained results which were completely the opposite of those secured by Mr. Warnerke. The reason he gives for this dissimilarity is that the dilatation and contraction of the eye will not permit of a perfect reading, whereas in the new sensitometer, containing the luminous tablet and magnesium ribbon for judging the different sensitiveness of dry plates, the latter can be more relied upon.

Since gelatine has been employed in the preparation of silver bromide solutions different chemicals have been employed to preserve the gelatine from decomposition, as gelatine can be kept during the summer for only a very short period without becoming, if not putrid, at least of no service in the manufacture of gelatino-bromide of silver plates. If employed frilling will result, with all its evils. Now, it appears that emulsions containing a small quantity of silver iodide have been free from this defect, in consequence of silver iodide being a powerful antiseptic. A great many experiments upon chemicals having antiseptic virtues have been carried out at l'Observatoire de Montsouris, Paris, and a list has been given. It appears that the bin-iodide of mercury is the most powerful antiseptic known, after which comes the silver iodide; in fact, it requires $\frac{1}{30}$th in weight more of salicylic acid to have the same power to arrest putrefaction than if silver iodide be employed. The attention of emulsion makers will be drawn to this fact, if it be true.

Mr. W. H. Harrison asks in the Journal for a good, flexible material for the light of a travelling lantern. "Lux" answered in describing a lantern [see diagram in THE BRITISH JOURNAL OF PHOTOGRAPHY, 1884, page 31]. The disadvantage of that lantern is that it cannot be held in the hand with ease. I informed Mr. W. H. Harrison of a simple "dodge" by which it can be carried with ease. (This kind of lantern I first saw at Messrs. George Mason and Co.'s establishment at Glasgow.) To make this lantern perfect solder a hook to each angle of the triangular tin top and bottom of the lantern. By putting three indiarubber rings from the top corners of the lantern to the bottom ones the lantern will be firmly held together. E. STEBBING, *Prof.*

25, *Rue des Apennins, Paris, February* 4, 1884.

CELLULOID DEVELOPING DISHES.

To the EDITORS.

GENTLEMEN,—I must have omitted to inform you that my new developing trays can be had in almost any colour, as you appear from your editorial notice to think that there are only white ones.

I have them in black, coral-red, and clear like horn—the latter with or without one end covered to form a well.—I am, yours, &c.,

8, *Kingsland Green, February* 4, 1884. F. W. HART

P.S.—In my advertisement the compositor has made me say that they are "all but breakable." My intention was to describe them as "all but *un*-breakable."—F. W. H.

AN ADAPTING SWING TO THE CAMERA.

To the EDITORS.

GENTLEMEN,—The sketches herewith show a very simple method I have adopted for obtaining a swing front to an existing camera constructed without a swing-back.

The one illustrated is a quarter-plate of the ordinary folding tailboard pattern, and all the alteration necessary is to make a new brass plate, marked A, with a slot in it, in place of the original one, and to cut away a similar slot in the woodwork to allow the clamping screw to traverse it, as shown.

Fig. 1 shows the camera set up as usual, *square;* and *fig.* 2 shows the swing in action. All that is needful is to slack the screw abovementioned, and re-clamp it in any required position in the slot. The focussing-screen will still remain vertical as before. The front will rise and

FIG. 1.

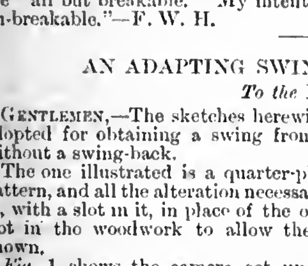


FIG. 2.

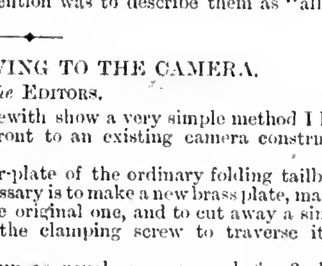

incline backwards, revolving about the hinge B at the bottom of the camera, and the part of the base-board attached to it will leave its bearing on the tripod; but, as this is only a small portion of the whole area of the top, it will not matter. There will be a small displacement of the image on the ground glass, so the lens will require lowering in its slide to suit.

I do not know if this be an original idea or not, and simply put it forth for the opinion of your readers as a means of converting an existing camera with very little trouble; at the same time, I do not claim any superiority (or, indeed, equality) to any of the ordinary means of obtaining the vertical swing, inasmuch as it will probably not come in for landscape work, but only for those positions that require the lens to look up at an object, such as a building.

I might mention that the swing cannot be used with a *very* short-focus lens unless specially mounted, because the dovetail slide carrying the back part must be behind the hinge B. For this reason, also, the camera must be set up, as in *fig.* 1, in order to open it out, after which the front may be inclined as desired.—I am, yours, &c., G. W. ATKINS.

Sheffield, February 4, 1884.

ENGLISH PHOTOGRAPHS IN FLORENCE.

To the EDITORS.

GENTLEMEN,—It will probably interest the readers of the Journal to know that the fine series of photographs by Messrs. Dixon, of the animals in the "Zoo," are commanding a considerable sale in Florence. They are a great attraction to the windows of Messrs. Brogi, Via Tornatuoni, opposite Vieusseux's well-known library, and the windows are usually crowded with gazers from morn till eve. Messrs. Brogi tell me they have sold a large number at five francs each (a high price for unmounted photographs in Florence), and they are sending for more.

I would make a suggestion that fine English photographs would get a good sale here during the winter season, and I am told that many of those of the animals in the "Zoo" were bought by artists who reside here permanently.

Some of my friends were much struck with the fine sea-pieces of Colonel Wortley in the late London Exhibition, also with those of Mr. Mayland, and some of yachts—racing and otherwise. It is probable that many of these would be likely to sell. If any of your readers are inclined to send specimens, addressed to "Captain Turton, R.N., Florence," or to "Mr. Brogie, photographer, Florence," it would soon be seen if they were saleable. They should be registered, as I have on more than one occasion lost parcels of sensitised paper sent me from England by post.

I have not had the opportunity of visiting the London Exhibition now for three years, but have sent to many of my friends in England, and have received but one report of the great advance made in photography during the last few years. The greatest compliment, however, paid to the advance of the photographic art was contained in a letter written to me last November by Sir Ralph Thompson, Permanent Under-Secretary for War. He says:—"I really thank you for causing me to go to the Photographic Exhibition. I had no idea that there had been so great a stride in photographic art within the last few years." This is a good tribute, and one unsought, in favour of photography.—I am, yours, &c.,

20, *Via de Benci, Florence, February* 2, 1884. FRANCIS W. TURTON.

Notes and Queries.

I HAVE several wooden dishes with glass bottoms. I want to use them for developing gelatino-bromide enlargements. Could you kindly let me know whether shellac or paint would be the better coating for the wood? Or is there anything better?—NOVICE.

F. C. S. asks—"Can tannin be added to gelatine without causing a precipitate? I have heard that it can, but I have not succeeded in doing so." ——In reply: Dissolve the tannin in glycerine instead of water, and then add it to the gelatine. A slight opalescence will be produced, but no insoluble precipitate will be formed.

G. F. B. W. asks if it be possible to take photographs by moonlight.——In reply: It is quite possible, but such photographs are more curious than beautiful, judging by those we have seen. But from what our correspondent remarks in the course of his letter we believe that instead of real moonlight photographs he probably means moonlight effects in photographs, which is quite another matter, and one easily accomplished in bright sunlight.

SARTOR RESARTUS observes:—"My present inquiry has reference not to a point of *practical*, but of *theoretical*, accuracy in the projection of a photographic view upon a plane surface. Is it possible to take a view which shall be theoretically accurate as one sees it in nature?"——In reply: If the photograph have been taken by means of a non-distorting lens and be viewed by one eye from a point distant from the picture equal to the focus of the lens employed in its production, then, we think, the conditions will be fulfilled of the theoretical accuracy mentioned.

QUERCUS inquires if it be fair in a man who is the proprietor of a photographic business to employ a first-rate operator for a few weeks in order to secure a collection of specimens of a higher class than any he had formerly been able to exhibit as having been taken on his own premises, and then to turn round coolly and say he would have to dispense with his services for the future, unless he (the operator) would consent to submit to a reduction in his wages amounting to nearly one-half that which was originally promised, and which was paid for three weeks.——As "Quercus" states the case, it is certainly unfair of anyone to act as this employer is said to have done; but we cannot offer any opinion unless made acquainted with the whole details of the agreement. Certainly we should like to hear what the employer had to say before we did so. Every story has two sides; but we do not compromise ourselves by saying that if the employer secured the services of the operator solely for the purpose of having him to make a few fine specimens, and then, without a proper reason, acted in the manner alleged, he was guilty of a dishonourable act.

T. S. Johnston inquires what is the cause of certain transparent spots which sometimes appear in his collodion emulsion negatives. He takes special care in filtration, employing for that purpose a piece of wash leather. He keeps his operating-room scrupulously free from dust, and he even filters his developing solution; and yet, notwithstanding all these precautions, he gets spots of the nature described. He would be grateful to any correspondent who would throw some light upon this annoyance.——We remember this question having been brought prominently before the readers of this Journal seven or years ago, without any solution of a definite character having been suggested. We shall be glad to receive the opinions of such readers as are conversant with the subject.

F. W. is desirous of ascertaining how it is that after preparing sensitive paper which will remain without being discoloured for months, and upon which he can get a good print, he experiences so much difficulty in getting it toned to the requisite tint that he is almost driven to despair. He employs citric, and sometimes tartaric, acid as the agent to confer durability, and floats the paper, after sensitising, back downwards, upon a thirty-grain solution of either of these acids.——We imagine that the error of our correspondent will be found in the great strength of the preserving bath, by which such a large amount of acid is left in the paper as to prevent its toning readily. If this be so the remedy is easy, consisting, as it does, in reducing the strength of the acid by varying stages until, instead of being thirty grains, there will be only five grains to the ounce of water.

R. B. Brown wishes to take some negatives from paper prints with a view to having them utilised in the production of transparencies for the optical lantern. He was present at the lantern exhibition of the South London Photographic Society, and very much admired some of the views which, as was stated at the time, had been obtained by copying prints on ordinary albumenised paper. He would be glad if we or any correspondent would give him some practical information by which he could be enabled to obtain transparencies under similar circumstances.——In reply: There is no difficulty about the matter. It is only requisite that a strong light be made to fall *directly* upon the picture to be copied; for, as we have frequently said, a side light renders noticeable the grain of the paper. Take the negative upon a gelatine plate and the transparency by collodion. We shall be glad to have the opinions of those who do not coincide in the recommendation here given.

Our attention has been called to a question in your Journal of the 1st inst. The querist asks to be informed where he can obtain a studio, and also refers to greenhouses. We are constantly sending out the latter, and have had some little experience in the former. Perhaps you will kindly make this known to your client.—Beckett Bros., Chelmsford.

I would suggest to "Publisher," who asks respecting the exhibition of a photograph of an athletic club, that he should stick a black patch over the gentleman who objects to being exhibited. It would attract as much attention, and all inquiries could be answered. I think that, unless the gentleman has an absurdly protuberant abdomen, &c., he would like the black patch removed.—H. R. S.

Exchange Column.

What offers in exchange for six cloud negatives 13 × 10, and three 11 × 6?—Address, C. R., 16, Gilpin-street, Liverpool.

Wanted, half-plate triplet lens, Dallmeyer's No. 1 preferred; good exchange offered.—Address, F. M. Pugh, 23, Bayham-terrace, Ealing Dene, W.

I will exchange a good old violin and bow, splendid tone, cheap at three guineas, for studio accessories.—Address, D. Blagrove, 73, High-street, Lewes.

I will exchange Bowman's hot rolling-press or other photographic apparatus for a set of first-class lantern slides.—Address, P. Swanson, photographer, Irvine, N.B.

I will exchange a cabinet-size lens by Lerebours, and a cabinet rolling-press, both in good condition, for anything useful in photography.—Address, A. Bishop, Station Hospital, Lichfield.

Wanted, Burrows and Colton's *Retouching*, also Bigelow's *Album of Light and Shade*, in exchange for Ross's focussing eyepiece, &c.—Address, A. Francais, 70, Myddleton-square, E.C.

I will exchange a Stanley five-inch square, sliding body camera and portrait lens, adaptable for small studio, for whole-plate landscape lens, or offers.—Address, T. J. Adams, Barnes-row, Carmarthen.

I will exchange a pair of posing chairs and photographic couch, by Cussons, of Southport, for dining table or accessories, or anything useful.—Address, W. C., 12, Westbourne-grove, South Kensington, London, S.W.

Wanted, in exchange for a large rolling-press, by Bury Bros., Manchester, plate size of 18 × 14, and some Seavey backgrounds, a good balustrade and pedestal. Send photo. to Imperial Studio, Beverley-road, Hull.

I will exchange a stereoscopic camera by Dallmeyer, with two dark slides, rising front, sky and foreground shade, almost new, for a view lens of a good make that will cover 8½ × 6½ short focus.—Address, C. Chambers, artist, 64, Mill-street, Crewe.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

Photograph Registered—

Arthur Silvena, Wellington-arcade, Glasgow. — *Photograph of "A Dream of Love."*

J. Traill Taylor.—Received. In our next.

J. K. T.—Inquire of Messrs. Barnard and Co., Oxford-street.

A. J. R.—Moule's photogen, perhaps, is lower in price. The oxyhydrogen light is of no use for portraiture.

J. C. Longford.—The formula is quite correct as given. Remember the toning and fixing is done in one operation.

Wicklow.—The only fault is that the prints are very much over-toned. The fixing bath is of a very suitable strength—certainly it is not too strong.

C. D.—So far as we are aware only one optician constructs his landscape lenses of three glasses. Most of the cheap landscape lenses consist of two glasses only.

A. B.—Some makers proceed one way and some the other. The castor oil will do no harm in the collodion. By alum, in this case, the common alum of the shops is meant.

A. J. Atkins.—The form of studio appears very suitable indeed. You might, with advantage, however, make the roof a little higher—say thirteen feet, instead of eleven feet six.

Novice.—The unpleasant smell is due to the paper being prepared with albumen which has become somewhat decomposed. Decomposed albumen is said to confer a higher glass than fresh.

S. J. B.—1. A pale, unobtrusive green or a French grey will be a good colour.—2. We should prefer the ground glass for the roof and the plain for the sides.—3. Better print the slides by superposition.

J. S. L.—The spots are caused by the hyposulphite of soda not being thoroughly eliminated before the negative was varnished, and damp silver paper being pressed upon it during the printing, which has stained the film.

C. H. B.—The paper is sensitised on the front surface, and printed on the back. Canada balsam, we imagine, will not hide the grain any more than will the poppy oil. Protosulphate of iron—not the ammonia sulphate.

Amateur.—Yes; pyrogallol and pyrogallic acid mean one and the same thing. From what you say it appears that it is the salicylic acid that is thrown out, and not the pyrogallol. The changes in colour the solution undergoes is due to the different degrees of dilution.

James Henwood.—If you register the photographs, each one will require a separate registration; or, if you register the mounts, only of course one registration will suffice. We do not understand clearly whether you desire to make the photographs copyright or only the mounts upon which they are placed.

C. Eskell.—It would almost look as if the plates were at fault—as if you had kept them so that some noxious vapour or other had contaminated them. Red-toned transparencies can be produced by the gelatino-chloride process. Not suitable for the exchange column, which is confined exclusively to exchanges and not to advertise special requirements.

J. (Wood Green)—If a solution of cyanide of potassium will not remove the stains, we fear the negatives are worthless. If the negatives are thoroughly freed from the hyposulphite before they are varnished a moderate amount of damp will not materially injure them, although it is always advisable to preserve them from moisture as much as possible.

Mancunium.—1. The wide-angle lens will certainly answer; but we should prefer to employ a lens with a larger aperture than that possesses, so as to secure a shorter exposure.—2. You may certainly construct a doublet out of the two lenses named; but you will have to employ a very small stop, and then the field covered will not exceed an inch or two square.

A. Bell.—If the varnish made with sandarac only does not abrade easily enough for you (though we should have thought it would), mix with it a little common rosin—say one-fourth the quantity of sandarac used in the varnish. Of course the larger the proportion of rosin used the less durability there will be in the varnish, as it will be very easily abraded.

C. C. B.—We have not received the letter which your correspondent has promised to forward to us; but your own communication and enclosure contain sufficient information on the subject to justify us saying that you are undeniably in the wrong. What possible objection you can have to supplying such simple and straightforward information respecting the business you have advertised as "lease, rent," &c., whether "old or newly-established, price," &c. (we quote from your own correspondent's letter), we fail to see. If, in answering such questions, you have to divulge any of the "secrets" of your business, then we can only say that the would-be purchaser is to be congratulated upon the collapse of the negotiations.

Received.—E. G. O.; A. R. Fenton (Collingwood, Australia); "May;" "Albumen." In our next.

Photographic Club.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 13th inst., the subject for discussion will be—*On the Development of Gelatino-Chloride Plates.*

Canary Medium.—We have received from Messrs. G. D. Scorah and Co., of Bradford, samples of the "true canary medium." This is a pale yellow paper possessing considerable substance, and is used, we believe, in the Bradford trade for packing purposes.

Photographic Society of Great Britain.—The next meeting of this Society, being the *annual* one, will take place on Tuesday next, the 12th instant, at 8 p.m., at 5, Pall Mall East, when the report of the Council will be read, the financial statement made, the election of officers will take place, and other business brought forward.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1241. Vol. XXXI.—FEBRUARY 15, 1884.

THE PERMANENCE OF PRINTS ON READY-SENSITISED PAPER.

It is frequently asserted that photographs—that is to say, silver prints—of modern production fade or deteriorate more rapidly than those which were formerly made; and we have more than once heard the opinion expressed that much of this fading is to be attributed to the very general use that is now made of ready-sensitised paper. If the allegation be true (?) that prints do fade more quickly now than formerly, it very naturally becomes a matter of importance to inquire into the reason, if one can be found.

At the last meeting of the South London Photographic Society the topic set down for discussion, in addition to the paper read, was—*Are Pictures upon Ready-Sensitised Paper Likely to be More or Less Permanent than those on Paper Freshly Prepared?* Owing to the late period of the evening at which the matter was brought forward it received very little attention. This is to be regretted, because the South London Photographic Society numbers amongst its members many of the oldest and most observant photographers, and the subject is one, in face of the allegations to which we have referred, that might well have been fully discussed. So far, however, as opinions were expressed at the meeting, they were to the effect that there was little or no difference in the permanence of prints made on ready-sensitised paper and paper of home preparation.

The term "ready-sensitised paper" is an exceedingly vague one, and it must not be assumed that papers under this title procured from different sources are all of the same preparation, and, therefore, are identical in properties. Every photographer knows that there is a wide difference between the working of the different samples now in the market. Some print very red in the frame, and others of a much more purple shade. Some tone very readily—quite as readily as paper of home sensitising—while with others there is a great difficulty in getting them to tone at all. With some kinds, with a very small quantity of gold, rich tones are obtained, while others will require a much larger proportion.

It is well known that some brands are perfectly sweet, indicating that they were prepared with perfectly-fresh albumen; others, on the contrary, smell most offensively, clearly showing that they were prepared with putrid albumen or with blood albumen, and, in some instances, the latter not of the finest quality.

With these facts before us, even if some prints on certain samples of ready-sensitised paper have proved more fugitive than corresponding ones on paper of home preparation, it must not be assumed that all kinds would of necessity yield similar results. This subject cannot be satisfactorily discussed, inasmuch as we are quite in the dark as to the preparation which the paper has undergone; for manufacturers, one and all, treat the formula and method they employ as a profound trade secret. One fact is certain, namely, that some descriptions of paper are prepared on much weaker baths than others, as may be proved by analysis; yet some of these weakly-sensitised papers yield prints quite as vigorous as the more strongly-sensitised, and they tone quite as easily.

With some kinds of paper it is impossible to get anything beyond a very warm brown tone without producing mealiness; but are the prints likely to prove more evanescent on this account? Those who hold to the opinion that deep purple tones are necessary to ensure permanence will not be slow in arriving at a conclusion—erroneous or otherwise. As a rule, ready-sensitised paper yields far more vigorous prints from a given negative than does that which is sensitised at home, even if the latter be floated on a much stronger solution. For this reason it might well be assumed that the ready-sensitised would produce the more permanent results of the two.

In alluding to the characteristics of different commercial samples of paper we mentioned that some had a most offensive smell (strongly suggestive of sulphuretted hydrogen), indicating that putrid, or blood, albumen had been employed in its preparation. Now many, we are aware, have a strong prejudice against using such papers, as they have an idea that it is liable to yield prints deficient in permanency. However, this idea is not always a correct one, as we have in our possession at the present time some prints produced fifteen or twenty years back which show no signs whatever of deterioration, yet the paper upon which they were made possessed the most offensive odour we have ever encountered in photographic paper. This experience with "stinking paper" can, no doubt, be confirmed by most practical photographers who have used it.

There ought not, one would think, to be much difficulty in arriving at a fairly correct conclusion as to which kind of paper yielded the most permanent pictures, if there be any difference, seeing that in many establishments both descriptions are in constant employment with negatives of a similar character, and have been for several years past. Ready-sensitised paper has been an article of commerce now for a period of fifteen years or more, although it may be said that it is only within the past few years that it has come into such general use; yet there has been ample time for observation. Still there is a difficulty in the way, namely, when fading occurs, can it correctly and without doubt be attributed to the paper itself, or may it not be due to something unnoticeable in the manipulations? It is within the experience of nearly every photographer that out of a batch of prints all produced at the same time, on the same paper, and, as far as is known, under identical conditions, some at times fade rapidly, while others prove practically permanent.

When discrepancies such as these occur with prints made, undoubtedly, on the same paper, it at once shows how difficult it is to arrive at a correct conclusion, when different kinds are compared, as to which of them really yields the greatest permanence. However, it would be instructive to learn the general opinion of those whose extended experience with both papers qualifies them to form a fairly correct judgment on the point, and we trust the matter will not be lost sight of until it has been duly considered and the point determined.

THE INFLUENCE OF ENAMELLING.

A statement was made at the last meeting of the Glasgow Photographic Society to the effect that the speaker thought the enamelling of paper prints a mistake altogether, and that in his experience they faded considerably quicker than plain albumenised prints.

As regards the value of the former expression it is, of course, a matter of individual taste, for which, as the proverb says, "there is no accounting." The function of enamelling is to destroy visibly the texture of the surface of the paper by imparting a glass-like, homogeneous surface which rivals that of a vitrified photograph upon opal glass or enamel; whence its name. So far, therefore, as mere appearances are concerned, the same reasons which, æsthetically, operate in inducing an admiration of a well-printed vitrotype upon enamel operate with equal force in evoking similar admiration for the enamel print upon paper. This estimate of enamels upon paper is shared by the great majority of photographers and also by the public.

The burnishing of prints is merely a compromise, or halfway house, between the perfect enamelled or *glacé* print and the plain albumen surface, and it is resorted to as an expeditious and cheap method of approximating, in a small degree, to the smooth, polished, *glacé* surface of the other. There are, however, numerous classes of photographs for which enamelling is quite unsuitable, these being, speaking in general terms, such as are of large dimensions; for example, collodion transfer enlargements, which, when stripped off polished glass and issued in that form, are simply vulgar—a vulgarity from which they are not always redeemed even by loading them with oil colours. For the highest class of large photographs it is probable that a surface as nearly matt as is consistent with preventing the image from sinking-in will ever be most preferred. The unglazed surface of the platinotype will always secure for it a high degree of admiration, while the carbon system is so facile as to be readily amenable to any requirement, from the most exquisite enamel-like polish to a canvas-like coarseness of surface.

While on this subject, we may observe that of all the various methods of securing the highest degree of brilliance, conjoined with the most absolute matt surface, none, as applied to silver printing, have surpassed or, probably, even approached to the Brinckerhoff "porcelain paper." This was introduced (nearly twenty years ago) under circumstances from which a prosperous career was augured; but, for commercial reasons connected with the patent—so, certainly, it was said—it became lost to the world just as the demand for it arose. No patent now bars the way. It is prepared by dipping the paper in a hot emulsion composed of three ounces of gelatine, six ounces of kaolin or terra alba, and a gallon of water. When dry, or partially so, it is immersed in a solution of alum or tannin to render the porcelain sizing insoluble.

A few years ago there was quite a mania for applying encaustic paste to the surface of photographs, with a view to impart a species of polish, and with an expressed hope of conferring durability. This was deposed by the introduction of the hot burnisher, which, like the use of double-albumenised paper, was adopted as a means of securing the highest surface by means short of actual enamelling.

The experience of the speaker whom we have quoted relative to the more rapid fading of enamelled than of plain albumenised prints is not borne out by such specimens of *glacé* work as we possess. We have examples of enamelled photographs produced long anterior to the introduction of alkaline gold toning; and candour compels us to say that, as regards fading, they are in quite as good a condition as some taken within the last five years on plain albumenised paper by a London photographer who is justly credited with being a master of the technics of his business. Nor have we ever seen, or even heard of, the fading of a photograph induced by enamelling. The encasing of the albumenised surface of the photograph in gelatine, and thus aiding in preventing the access of deleterious atmospheric influences or noxious gases to the image, should, in reality, conduce to the permanence of the image; and we believe that, if skill as well as care have been brought to bear upon the operation of enamelling, the photograph will be rendered more permanent by this treatment than without it.

We are quite aware of all that was claimed for an application of collodion as a varnish to prints, a few years since, with a view to imparting a greater degree of stability to them, and we are further aware that an effect was produced quite contrary to that anticipated and desired; but in enamelling, as now practised, inert gelatine alone comes in contact with the image, although collodion takes a part in the formation of the enamelling film as an external coating. But from the very nature of the modern methods of enamelling the collodion is rendered in the purely pellicular form, and the ether and alcohol are all evaporated previous to its being brought in juxtaposition with the gelatine which is sandwiched in between the print and the collodion, so that this latter is thus doubly incapable of affecting the stability of the photographic image.

From the foregoing considerations it will be seen that we do not sympathise with the remark made at the Glasgow Photographic Society, the substance of which we gave at the commencement of this article.

ANIMAL PORTRAITURE.

It appears to us that the obtaining of correct portraits of domestic animals—we have in our mind when thus writing horses and dogs more particularly—is, comparatively speaking, a neglected art. Mr. Dixon has done for lions and tigers what a hundred others could do for dogs and horses, with both profit and *éclat*, and with a hundredth part of the trouble involved in the production of pictures so grand as the celebrated studies by that gentleman. That there is or would be a demand for such photographs scarcely admits of doubt. The wonderful pictures by Landseer do not owe all, nor even, we believe, the chief, part of their attractiveness to that human expression he so deftly conveys into their faces. Every Englishman loves a horse or a dog, and it is the portrait of the dog and not its expression that appeals to the public. Who is there that does not remember *Dignity and Impudence* (not the original title of the picture, by the way)? And is it not simply the portraits, in quaint juxtaposition and arranged with great art, it may be, of two dogs—a grand animal and its small friend—that compel admiration?

Yet, we think, most of our readers will agree with us that there is little in that particular picture which, granting the skill to design and the brain to conceive, could not be achieved by photographic means. What a run such a picture would have! We do not suggest an imitation of *Dignity and Impudence;* that would be base art. We merely allude to the picture as a guide to show the lines in which photographers might work; and we see no reason why a picture almost as effective should not be made by a photographer possessing artistic feeling and a love for animals.

The absence of colour, which is the characteristic of photography, would in this case be a positive advantage. It has been said—and, we believe, with considerable truth—that it was the engravings of Sir Edwin Landseer's pictures that made him so famous; yet we would not go so far as to say it was the skill of the engraver. No doubt his animal pictures were engraved with rare skill, but there was fidelity to the original painting as well. We have before us as we write a number of photographs of studies of heads of deer and sheep in coloured chalks by Landseer. Every touch of the master is shown and has been so successfully rendered in the photographs that no one would imagine the original pictures were coloured. They are as successful as the best engraving could be.

Again: photographic representations of animals, if well done, should form references of great value to breeders and lovers of all live stock. In this country the breeding of animals is carried to a perfection that is looked for in vain in any other land. A series of photographs of some animals that, in bygone years, were the foundations of a particular breed, would now be priceless, to fix the type and show the progress made. Similarly, photographs taken at the present time would be of value to the breeders of the twentieth century. Perhaps it might be a little difficult at first to get such photographs into large circulation, for there would be less chance of their verisimilitude being injured, as so often happens in a painting. He would be a very conscientious artist who could ignore his patron's hints to paint out any defects which the owner's skilled eye had detected. Let his subject be a sheep, and the end aimed at length of wool; a cow, and peculiarities of build; a dog, and special characteristics of coat and form—it will be strange if in a painting points of coat or build or form do not get exaggerated under the eye of the patron, if only by reason of the reiterated stress laid upon them.

At the present day, when books and periodicals are devoted to almost every hobby of this kind it is possible to ride, the need for correct photographs is great; for the engravings and chromolithographs that are employed for the purpose are often worse than useless. In no case, perhaps, is this more glaring than in canine portraiture. When we see shows held many times during a year, with upwards of a thousand animals exhibited in each, it may be guessed what a valuable property a highly-bred animal must be to its possessor, and we may be quite sure that no picture would be allowed to be sent abroad in which defects were at all accentuated; the consequence is the multiplication of thousands of really useless representations.

Whether for *genre* pictures or as technical portraits of typical specimens of breeds, the photographing of dogs might take a fairly important place. Unlike horses and cattle they can be brought to a studio, where all that is required can be done, and we feel confident that a ready sale would be found for pretty studies or more ambitious pictures, while an increasing demand would arise for portraits of celebrated or champion animals.

It requires, however, some little knowledge to take the latter class of picture, and considerable patience. The fancier will not be content with a picture only of his dog—he will require a portrait; and if certain points that he knows of (but which very likely the photographer does not) should be lost sight of in the portrait obtained he will not care for it. We do not think it would pay many professional photographers to undertake this class of work for private individuals unless very well paid or a large quantity were ordered.

As an example of what we mean, let us take a pug dog, one of whose "points" is to have his tail tightly curled and lying close to his body on one side. No picture would be accepted should "doggie" uncurl it in excitement or nervousness caused by his novel surroundings. A terrier, as a rule, is easily taken, and the pricking of his ears in the endeavour to attract him gives him a lively and terrier-like appearance; but the case is very different when a majestic Mount St. Bernard or a huge mastiff is the subject. They are too self-contained to be represented pricking their ears; and a photograph so portraying them, if not absolutely rejected, would not be cared for. Some dogs must carry their tails in a certain fashion. We have seen a picture, that has been largely sold, in which the photographer was commissioned to make a highly-finished opal picture with a "tail to order," and this opal was then copied from.

Again: the limbs must be straight and regular. No pretty positions will be allowed by the fancier, lest through the necessary foreshortenings the public should think the animal deformed. Finally: we must lay great stress upon getting the animal's body exactly "square" to the camera in all studio work; for, when any but the longest focus lenses are used, the slightest deviation from this position will place the body in perspective, so that if the head be nearest to the camera it will be magnified, while the hind-quarters will be dwarfed and appear weak. If the reverse be the case the head will look poor and feeble and the stern unduly proportioned.

For the professional photographer, as we say, we should think such work only worth doing on special terms; then he might make it worth while to spend time, and produce pictures likely to have a long, steady demand. For the other kind of canine subjects the ground is comparatively clear, and the successful worker in it should reap a rich harvest for the practice of his skill and patience in that class of work.

Our attention has been called by the inquiry of a correspondent to a slight injustice apparently done to Mr. B. J. Edwards in our advertisement of the frontispiece to our Almanac for 1884. As our correspondent suggests, many readers would be glad to know upon whose plates the "charming picture" was taken. We have pleasure in doing what is needful.

We shall next week have something to say on the subject of Mr. Geddes's remarks on *Halation* made before the Dundee Society, the report of which reaches us too late for this week.

We must not be understood to endorse all the speculations put forth in the interesting article of Mr. H. S. Starnes in another column; for, to tell the truth, we have scarcely yet had time to digest it or to define the exact meanings of his terms "counter-force to actinism" and "density." The term "actinism" has for years been discarded by scientific men, so that its "counter-force" must, from a scientific point of view, be a doubtful quantity, while, in the matter of "density," Mr. Starnes seems to get rather "mixed" between *optical* and *mechanical* density.

The state analyst of Boston, Mass., has devised what he considers a "more simple means of inducing rapid filtration" than any he has yet seen. He pumps air from a Fletcher's bellows "to *any* desired pressure," and applies the pressure by covering the funnel with a piece of glass an inch thick, six inches square, and provided with an india-rubber cushion cemented to it; through a hole in the middle of this plate he forces the air into the funnel. As this glass may weigh perhaps about three pounds, it would afford a pressure upon a funnel of three inches diameter of less than half-a-pound to the inch. The value of such a pressure we leave to our readers to gauge. This filter, if of any practical use whatever, is not likely to be serviceable for emulsion filtration.

An attempt is about to be made in the Senate of the United States of America to reduce the duration of the existence of patents to five years. It is believed the measure will be carried.

A continental chemist, M. Gruning, having found that the preparation of hydrobromic acid by the usual methods of distilling sulphuric acid and bromide of potassium, or sodium, always give an acid of indifferent quality, has devised a method in which pure phosphoric acid replaces the sulphuric acid. In a flask of about a pint capacity are placed three ounces of coarsely-powdered bromide of potassium, and five and a-half ounces of phosphoric acid of 1·304 specific gravity. A spirit lamp or Bunsen burner will supply sufficient heat to cause the acid to distil over. The first part of the distillate may contain hydrochloric acid from the presence of chloride in the salt, and in this case must be rejected.

We have often had occasion to draw attention to the use of alcohol in withdrawing water from gelatine films, whether in the form of gelatino-bromide plates or carbon prints, yet we see that an operation of an almost contrary nature is recommended, though the contradiction is more apparent than real. It is stated that alcohol can be dehydrated by suspending it in sheets of pure gelatine, which will gradually and slowly absorb the water. The alcohol remains bright and clear, though the gelatine becomes soft. The process is very slow.

Workers in special trades and professions have often been found to possess immunity from certain contagious or infectious diseases in a manner that is not always clearly understood. It would be an interesting problem to ascertain to what extent photographers might be so invulnerable to the attack of germs, seeing that they—at anyrate in the pre-gelatine days—almost lived in a special atmosphere, ether, acetic acid, hydrocyanic acid, and soforth being daily inhaled by them. One particular salt (hyposulphite of soda) would seem to offer special privileges to them, as it has been found by Dr. Duncan that both as remedy and prophylactic it is beneficial against diphtheria. In instances where districts were suffering from an epidemic of that disease he found that its further spread was arrested by the administration of small quantities of that salt to healthy persons.

We hope Dr. Duncan's views may be correct, for the prevention of this fell disease by such simple means would be a boon of incalculable value. We are, however, doubtful upon the matter; for we well remember the same salt being recommended, a number of years ago, as a certain prophylactic against the rinderpest at the time that complaint was devastating the herds of the country. It was found useless!

A somewhat singular result followed the recommendation to use hypo. at that disastrous period. Such an instant demand arose for the salt that the manufacturers could not supply all that was required. For a brief period the price (which, since the days of the discovery of its photographic usefulness, when it was worth a guinea a pound, had been a continually falling one) went up in a brief space of time to almost double the then average market price.

Since, however, all these impure atmospheres have almost departed from the *atelier* of the photographer, there may be less expectation of him enjoying any especial immunities; but a new hope may arise. Dr. Carter Moffat has designed an instrument called the "ammoniaphone," and Mr. T. Gilbert Bowick is its prophet. The latter gentleman has noticed that free ammonia exists in the air of Italy to a larger extent than "even in the atmosphere of many parts of the seacoast of other countries." A number of small lakes are largely impregnated therewith, and we know that Tuscan ammonia from the lagoons is an article of commerce. The doctor above-named is an ardent chemical investigator, and has been investigating for nine years in this connection. The logic is beautifully simple—Italians are splendid singers; they breathe more ammonia than the rest of the world. Problem: find a means of giving the same benefits to ordinary people, and the result will be equally fine tenor and bass, soprano and contralto. The audiophone solves it, and Dr. Carter Moffat proves it. His voice, originally very weak, harsh, and destitute of intonation, has by the use of the ammoniaphone become "a pure tenor of extraordinary range!" In the course of a decade England ought to possess an army of "pure tenors" if alkaline development continue.

Pandastic is stated to be made by burning, without injuring it, a mixture of bisulphide of carbon and hyponitric acid. It burns quietly with a brilliant white light, and, we read, may be used for spectacular effects to represent moonlight. The liquids are to be kept separate, and burnt, somewhat after the fashion of an oxyhydrogen light, by bringing them together upon a dish which has to be kept quite cool—rather a difficult feat, we should imagine!

Heliophanite, or sunshine, is the name given to the mixture when phosphorus is dissolved in the bisulphide—an addition which greatly increases the illuminating power of the flame.

Pandastic is scarcely a mixture advisable for use in the everyday practice of the photographer; for, under suitable conditions, it explodes with terrific violence. In truth, the mixture is devised specially as an explosive, and from experiments carried out at Cherbourg it would seem that dynamite was a harmless toy in comparison with pandastic.

We are forcibly reminded of Sir Edwin Landseer's picture of *Dignity and Impudence*—alluded to in another page—by an incident that has recently caused considerable amusement throughout the country and is going the round of the papers. An actor who in a Christmas pantomime "makes up" as the Right Hon. W. E. Gladstone has been photographed in character as the "Grand Old Man," and has sent a copy to the Premier, who, so far from resenting what the groundlings would term an impertinence, has honoured the actor with an acknowledgment through his secretary, who, in signifying the acceptance of the picture, was instructed to thank the actor for his courtesy, and to say that Mr. Gladstone had very much pleasure in accepting the photograph, which he thinks testifies to a clever impersonation. Professional photographers often tell their sitters they are not good judges of their own portraits, but in this instance we can bear testimony to the truth of Mr. Gladstone's verdict, for Mr. Bannister's "get up" is singularly like its prototype, and is deficient only as regards the feet.

CAPTAIN ABNEY, F.R.S.

In presenting, this week, the second of our series of portraits—that of Captain Abney—it is scarcely necessary for us to enter into any elaborate introductory remarks. Captain Abney has for many years past played such a prominent part in contemporary photographic history, and his name is so intimately identified with recent progress in the science, that our readers, one and all, must be perfectly familiar with all but his *personnel*.

It would be superfluous to allude in detail to the numerous contributions made by Captain Abney both to the literature and science of photography. In addition to many papers read before different scientific bodies, as well as original articles which have appeared in our columns, he is the author of several works on photography, and many communications from his pen have appeared in the *Philosophical Transactions*. For some years in charge of the photographic department of the Royal Engineers, it became Captain Abney's duty to direct the photo-astronomical operations of various government expeditions for the transit of Venus and eclipse observations; and, though his official connection with Chatham has ceased some years, he is still practically the chief adviser in such matters. On the relinquishment of his duties in the higher branches of the science, Captain Abney was enabled to devote more time to the practical side of photography—with what success his labours in emulsion phototography sufficiently testify.

Captain Abney is a Fellow of the Royal Society, the Royal Astronomical Society, the Chemical Society, the Institute of Chemists, and is on the Council of the British Association. Before the first-named Society he, two or three years back, delivered the Bakerian Lecture, the subject being a photographic one. He has just retired by rotation from the vice-presidency of the Photographic Society of Great Britain. Our portrait is from a photograph by Messrs. Adams aud Scanlan, of Southampton.

"ACTINISM AND WAVE-LENGTHS."

Before replying to the various questions raised by Messrs. Kirkby and Macdougald, in your last issue, I wish to say that I was perfectly aware that my statements were contrary to the generally-accepted theories of light. But old theories did not explain to my mind certain points which practice has proved to be facts. I therefore tried to the best of my ability to find an explanation for certain phenomena which have been discovered since the accepted theories of light were first put forth. The subjects of my articles were not written on the spur of the moment, but were the results of months of thought. They were written and published with a feeling rather of dread than of arrogance and self conceit, for which Mr. Macdougald evidently gives me credit.

Of course theories are only the *supposed reasons* for certain phenomena which practical knowledge proves to us to be facts; if theory will not explain these facts, so much the worse for theory. If anything is discovered which old theories will not explain we cannot alter the fact of its existence; the only thing we can do is to try to find a theory that will explain it. It is of no use thinking that the world is going to stand still, and that all the discoveries of the present day will be suspended just because they clash with the theories of fifty years ago, which were only the supposed explanations of certain facts that had been discovered up to that time.

I think theories are often started in the following way:—Someone gives a supposed reason for certain phenomena, others without going into the matter accept it as correct, and when it gets into the textbooks people do not think of questioning the matter; but, if anyone does, he is looked upon almost as a lunatic for doubting a well-established theory, when, perhaps, at first it was only given as a possible explanation, and no one has since thought of going into the matter. How often, in the history of an invention, do we not find that the casual hint of another person will overcome a difficulty which had, perhaps, cost the inventor months of thought without giving him the key to the mystery.

The reason my articles were written was to give a few hints to far wiser heads than mine as to the direction in which I thought an explanation could be found for certain facts that have been discovered of late years in connection with photography. My reflecting lamp—which was only a little rough deal box and a piece of tin—*has* served as a hint to Mr. A. Cowan in making his lamp, so that he has been able to expose a rapid plate for *fifteen minutes* to a safe light, besides having a more luminous light to work by than hitherto. He had previously obtained a deposit in *five seconds*. Mr. Cowan tried the idea practically, with the above excellent results; but Mr. Macdougald has endeavoured to see what bearing the subject has on old theories first, without considering that one ounce of fact is worth a ton of theory.

About forty years ago the photographic experimentalists of that time gave certain theories, or supposed reasons, for the action of light on different salts of silver. In their experiments they found that, when copying the solar spectrum on a surface of iodide of silver, the actinic power of light only affected the film where the violet, indigo, and blue rays fell, and that the green, yellow, and orange rays had no power on the film. They also found that a bromide of silver film was slightly sensitive to green; but, as that colour could be made with blue as one of its component parts, they therefore called violet, indigo, and blue actinic rays, and supposed that these three colours were themselves the forces that acted on the

CAPTAIN W. DE W. ABNEY. R.E. F.R.S. &c.

INK-PHOTO, SPRAGUE & Co LONDON

film, and that actinic and luminous spectra were totally distinct from each other, and that light was split into three divisions by the prism, namely, heat, luminous and actinic rays. Since that period these theories have scarcely been questioned. We have gone on accepting them as correct without asking how far later discoveries have affected them.

But what important discoveries practice and experiment have brought to our knowledge during those past forty years! For instance: we have found actinic force not only passing through red and yellow glass, but Captain Abney and others have found it, even with the ultra-red rays, beyond visible light. How will the old theory of the three actinic rays explain why actinic force is found at the other end of the spectrum? How is it that a bottle of collodio-bromide emulsion can be placed in bright daylight for hours, and, after well shaking up the bottle and coating a plate in the dark room, that a perfect picture can be obtained on development, showing only a slight trace of fog.

Again: how is it that by putting a gelatine plate or emulsion in a bath of bichromate of potassium we can eleminate fog, even when produced by light? How is it that friction will have exactly the same effect on a gelatine film as light? How is it that (as mentioned by the Chairman of the Leeds Photographic Society the other day) a gelatine plate can be exposed, and after having been put aside for a time exposed again, without any trace of the first picture being found on development? Or how——, but I think I have given sufficient questions for the present for Mr. Macdougald and his well-established theories to answer.

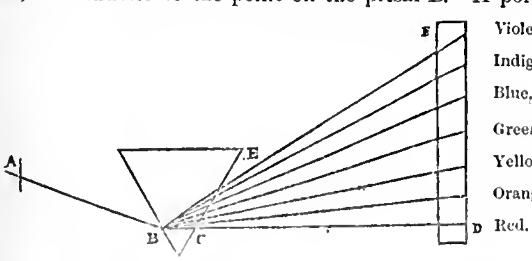
I have been working out experiments on these subjects, and have been able to find, to my satisfaction, solutions of them all; but they tell so heavily against the present accepted theories that, for weeks past, it has been a grave question to my mind whether it would not be better for me—a young experimentalist—to drop the subject rather than have to fight, at first alone, against these old-established theories and prejudices, to say nothing of running the risk of being the butt of attempts at scarcely-veiled sarcasm, of which Mr. Macdougald's articles are such fine examples. He says that I have the "courage of my convictions." What else *can* he expect? If I did not say what I thought where would be the use of thinking? Would he have me wait until he and the well-established theories have explained the various difficulties which I have mentioned above?

But to go to a more pleasant subject, viz., to reply to the interesting questions put to me by Mr. W. Horseman Kirkby.

Firstly: Does red glass bring the various wave-lengths of light all to one length in their passage through it? or does it absorb all the other colours but that of red?

I hope to prove farther on that the former is correct. To my mind the supposed absorption or filtering out of all rays but the one colour has always been the weakest point in the generally-accepted theory of light, and is one that I have never seen satisfactorily explained. Why should the action of light be different to everything else in nature—even to that of sound? If all the other rays but the one are filtered out what becomes of them? I think even the prism shows that my theory—that wave-lengths are a counter-force to actinism and are governed by the density of the substance which transmits the light—is correct.

We will suppose that a pencil of sunlight has passed through a hole, A, in a shutter to the point on the prism B. A portion of



this pencil of light is refracted to C, and then on to D, to form the red end of the spectrum. In its passage it has to pass through the least dense portion of the prism, so that the loss of power in passing is less than it would be in passing to any other part of the spectrum. But there are other portions of the pencil of light passing through the prism at various angles of refraction, right up to the point E, and then on to F, which forms the violet end of the spectrum. Now these portions have to pass through a gradually-increasing density in the glass of the prism which will absorb a corresponding increase of the propulsive power from B. This will explain why the wave-lengths, or counter-force to actinism, gradually decrease from the red to the violet end of the spectrum; but the propulsive power of the various rays when starting from the point B would be equal.

Perhaps it would help to make my meaning plainer if I endeavoured to represent the various powers of the wave-lengths by numbers. Let us suppose that each ray at the point B is equal to 15 parts: 5 of these parts in passing from B to C will be absorbed, which will leave a force equal to 10 at the point C, which number would represent the power of the wave-length at the red end of the spectrum; but the light in its passage from B to E would absorb (let us say) 10 parts, which would leave the counter-force to actinism at the violet end of the spectrum at 5 parts, or half the wave-power of the red. Any transparent substance which is of exactly the same density as the prism from B to C will transmit red light; or, contrariwise, if any substance transmit violet light, the ray of light has in its passage through the medium met with the same resistance as it would in passing through the prism from B to E.

From this I argue that coloured glass—say red—does not absorb all rays but the red, as maintained by old theories; but that light in passing through this coloured medium has lost the smallest amount of power in its passage, and has, therefore, the strongest counter-force to actinism remaining. The various colours of the spectrum would, therefore, be caused by the amount of force which is taken up in passing through the prism at the different angles of refraction.

Secondly: Are the combined wave-lengths of yellow and green greater than that of red? I saw the force of Mr. Kirkby's objection when I wrote the paragraph, but it was the only way I could see of explaining it. If we put pieces of yellow and green glass between a sensitive plate and white light the combined counter-force to actinism of the two glasses is more than if red glass were used alone; but the light passing through the two glasses appears to the eye almost a white light, or at least but faintly coloured. This matter seems to me to be governed by the same laws as those which, under certain circumstances, produce from the colours blue and yellow, pure white light.

Thirdly: By using quartz lenses I mean that a gelatine film will be found to be more sensitive to the violet rays than if glass lenses are used.

Fourthly: I should have said that a corresponding amount of the boiled gelatine should be taken, instead of the few grains of gelatine which are boiled with the silver bromide during the preliminary stage of emulsion-making. Thus, if a formula gave twenty grains as the necessary weight of gelatine, we should take one ounce of the boiled gelatine in lieu of them. Of course the bulk of the gelatine should not be boiled. The reason, I think, that this way of preparing the emulsion is best is because one only requires to heat it to about 130° Fahr., so that the particles of the silver bromide cannot sink to the bottom of the vessel and "club together" as easily as they would if the gelatine were made more fluid by raising it to boiling-point.

In a future communication I will reply to Mr. Macdougald's questions. However, before then I hope to have the pleasure of reading his paper, which is to "settle once and for all the vexed question of dark-room illumination." HERBERT S. STARNES.

SODIC SULPHITE: ANOTHER VIEW OF THE QUESTION.

AN interesting article appeared in last week's number of THE BRITISH JOURNAL OF PHOTOGRAPHY, from the pen of my friend Mr. B. J. Edwards, giving his reasons for objecting to the use of sodic sulphite in combination with pyrogallic acid as a developer. Whilst giving his motives for dissent, Mr. Edwards also gives what he states to be the *primum mobile* for its use; and this forms such a very small portion of the real facts that I ask for space to give once more, though I have often, by your favour, stated them in these columns, the actual reasons which induce those who use sodic sulphite to do so. They may be divided into three heads:—

1st.—That the negatives being of what is known as wet collodion colour, yield nearly double the number of prints that can be obtained from a negative developed with pyro. without sodic sulphite. "Time is money," and an enormous gain is thus found in publication work and in the execution of business orders in winter time.

2nd.—That the developing solution with sodic sulphite remains clear after use, instead of becoming at once, on mixing, thick and turbid, throwing down a solid opaque deposit, from the fact that oxidation commences when the ammonia and pyro. come together.

In plain English, instead of the pyro. being precipitated the sodic sulphite prevents oxidation, and gives the whole of the materials to be used in forming the image. Hence a great saving in pyro. and in time, because one portion will develope a number of plates. But one of the greatest charms in the use of sodic sulphite is that the most delicate fingers are kept perfectly clean, and dishes also. This alone would make its use certain.

3rd.—That the image corresponds in colour with the retouching pencil. Thus the exact value of each touch can be estimated. Again a great saving of time and labour.

Now, when all these considerations come to be added together, a strong case is shown. It is not correct that the use of sodic sulphite is decreasing—far otherwise. It is a large and important manufacture, both here and abroad, and its use is daily increasing. Some difficulty and discouragement arose at first from want of a definite formula; but since the adoption and full recognition of my method (as given in these columns) of making a boiling, saturated acid solution this has disappeared.

On the continent the colour of pyrogallic negatives caused the ferrous oxalate system to be adopted; but the sodic sulphite is now fast gaining ground. Excellent sodic sulphite is now being made by Messrs. Malétra et Cie, manufacturing chemists, Rouen, so that our French workers get it just as good as we.

Mr. Edwards says he finds that the scale of gradations of tone is distinctly shorter in negatives thus developed. In this I differ entirely from him. They are really shorter where anything like alum and citric acid is used to clear negatives, instead of using sodic sulphite. My belief, after having had excellent opportunities of judging, is that sodic sulphite is a distinct advance, and has remedied many of the minor objections to dry-plate work.

SAMUEL FRY.

STANNOTYPE.

No. III.

THE transparency having been obtained, the next step in the process consists in the formation of the relief or printing mould. For this purpose a tissue is employed many times thicker than ordinary carbon tissue, in order to afford a sufficient degree of relief, and containing a very small proportion of colouring matter to enable the light to penetrate to as great a depth as possible.

The special relief tissue is obtainable commercially, and differs from ordinary carbon tissue in being made in small sheets instead of bands, as the great thickness of gelatine required will not permit the long rolls of paper to be coated in the ordinary manner. For the benefit of those who may be desirous of making the tissue experimentally the accompanying directions are given. The following formula for the "mixture" is a good one, but the proportion of hygroscopic matter may be varied within certain bounds to suit particular circumstances, its function being merely to render the thick tissue pliable and prevent its cracking. Take—

Gelatine	4 ounces.
Glycerine	½ ounce.
Sugar	180 grains.
Colouring matter	*quant. suff.*
Water	16 ounces.

The character and quality of the gelatine employed is a matter of paramount importance. It must be a soft and easily-soluble kind, or the development of the relief will occupy an inconveniently-prolonged period; and it must be free from all traces of alum or other contaminations, accidental or otherwise, which are likely in conjunction with the bichromate to cause insolubility. Most of Nelson's will answer admirably, the cheaper samples of "flake" being quite good enough for the purpose.

Place the gelatine to swell in the water, having previously dissolved the glycerine and sugar therein; leave it for some hours in order that it may become perfectly soft, or at least as soft as the small quantity of water will permit. Care must be taken, especially in the earlier stage of the soaking, that the gelatine is pressed below the surface of the water and well stirred about in order that the absorption may be uniform, otherwise on applying heat the solution will take place slowly and with difficulty. When the gelatine has thoroughly swelled the vessel containing it is immersed in hot water, the contents being well stirred until completely dissolved, when the colouring matter is added.

With regard to the last no definite rule can be laid down as to quantity. The colouring matter might be omitted altogether, were it not for the difficulty—if not impossibility—of judging the progress of development of a colourless relief. It was at one time supposed that the colouring matter was necessary to prevent loss of sharpness by the spread of light in the gelatine film, but this has been found not to be the case. It will be seen, then, that, so far as the *formation* of the relief is concerned, the colouring matter plays a comparatively useless part; in fact, it may be said to be actually detrimental, inasmuch as by obstructing the action of the light it limits its power of penetration, and hence the depth of the relief as well as increasing the exposure necessary. The only rule to be followed is that the mixture when spread upon glass to the requisite thickness shall be just short of absolute opacity; that is to say, shall show daylight through when held up to the sky.

In order to arrive at this, actual experiment is, of course, necessary, as everything will depend upon the thickness of the tissue and the nature of the colour employed. It should be borne in mind that for the reasons stated above the quantity of colour, or, rather, the degree of opacity of the tissue, is capable of modifying the character of the relief, and may be utilised as a power for that purpose. Thus, the more opaque the tissue the shallower will be the relief, owing to the arrest of the light's action, and so a tendency to flatness is produced. For this reason a deeply-coloured tissue will be found more suitable for negatives with strong contrasts, and *vice versâ*. It follows that the substitution of an actinic colour, such as blue for black, acts in the same manner as reducing the opacity; whence blue tissue may be employed with advantage with very soft negatives.

Knowing the thickness of the layer of coloured gelatine which will be required to form the tissue, it is an easy matter to test for the quantity of colour required by examining a layer of the proper thickness held in suspension in water. If a measured quantity of any liquid preparation, such as those readily procurable at the artists' colourman's, be diluted with water until it begins to show translucency when placed in a glass tube of the necessary diameter, the end is gained. A slightly-modified plan is the following, which has been found to work with the quantities and measurements given in the present article:—Into a narrow test-tube, as nearly as possible half-an-inch in diameter, one ounce or any measured quantity of water is placed, and to this is added, drop by drop, the liquid colour until opacity is produced; if very concentrated, the colour should be first diluted. Proceeding in this manner it is found that a single drop of liquid colour of a certain make suffices to give the requisite opacity to two and a-half ounces of water, from which data it is easy to calculate the quantity necessary for any bulk of mixture.

As to the colour employed: the choice is immaterial, though Indian ink or China ink is usually selected, chiefly on the score of convenience. Prussian blue is frequently employed; in fact, any colour may be adopted if due attention be paid to what has been said regarding the modifying effect of the colour upon the opacity of the tissue and the bearing that this will have on the depth and printing qualities of the relief. The mixture now requires filtration, which is an operation of the utmost importance, as the minutest speck of dust or other foreign material will produce a corresponding defect in the relief. In consequence of the thickness of the gelatine solution and its ready tendency to set, it is almost absolutely necessary to employ special means to retain it in the liquid state during filtration. The filtering medium should consist of, at least, four folds of muslin, and if the filter be placed in a warm oven, or near a bright fire, the heat will suffice to keep the mixture fluid. Felt and similar filtering media are useless for this purpose unless the filtration be performed under pressure. The exhausted-flask arrangement of Mr. C. Beckett Lloyd answers for the purpose; but even with that the filter soon becomes clogged.

The mixture being ready there are several ways of converting it into tissue, the object to be aimed at being the production of a perfectly even layer of considerable thickness. The method recommended by M. Léon Vidal consists in immersing in warm water a sheet of glass, and a sheet of good, even photographic paper. In a few minutes both are withdrawn, placed in contact, and the surplus water removed by means of the squeegee. The paper-covered glass is placed upon a previously-prepared levelling-stand to receive the mixture, which is spread by means of the finger or a glass rod. When set the plate is put in a drying-closet or warmed room until thoroughly dry, when the paper carrying the gelatine film is separated from the glass. This plan has the disadvantage that the upper surface, which is exposed to the air in drying and may attract dust, besides exhibiting other defects, is the one which comes in contact with the *cliché* in printing, and thus retains on the relief all imperfections. It is, moreover, difficult to retain a sufficient quantity of the mixture on the plate.

Mr. Woodbury's plan consists in pouring the mixture into shallow plate-glass trays previously coated with ox-gall and accurately levelled; when set these trays are placed on the racks in the drying-room—an apartment heated to about 70° Fahr.—where they dry in about a couple of days. Sheets of paper of the required size are then wetted and squeegeed on to the dry gelatine surface, and the compound films again placed on the racks, where they now dry in about a couple of hours. By performing the first drying before applying the paper a great saving of time is effected, as the surface of gelatine is then freely exposed to the atmosphere. The small quantity of water subsequently absorbed by the gelatine from the paper is rapidly got rid of. The tissue may be kept in this state until required for use, when, previous to sensitising, it is stripped from the glass by inserting the point of a penknife under one edge, when the whole comes away with the greatest ease and with a beautifully-smooth surface. The smooth surface is a double advantage: it secures close contact in the printing, and, having been in contact with the glass, has been protected from dust and other defects.

The method we have ourselves adopted is substantially Mr. Woodbury's. Plate glass is polished with wax or talc, collodionised and converted into a dish by means of strips of paper pasted round the edges. This is then levelled and filled with a measured quantity of the mixture as already described, and treated in a similar manner.

With regard to the thickness of the tissue it is impossible to lay down any definite rule, as, like the variation in its opacity, so its different thickness has a bearing on the depth of the relief. Too thin a layer must be avoided, as it is impossible to make up for its want of depth; too thick a layer is only objectionable on the score of economy, and in taking longer to develope, dry, &c. A convenient thickness for the gelatine film when dry we have found to be from one-twenty-fifth to one-twentieth of an inch; with the mixture of which we have given the formula such a thickness is obtained by allowing for each square inch of surface about forty minims of the mixture. Thus for a 12 × 10 plate about ten ounces of mixture will be required; and this will form a layer, when wet, of the depth of about one-fifth or one-sixth of an inch, drying down to about one-quarter of that.

The drying of these thick films is a tedious operation, unless hastened by heat or by means of chloride of calcium. It is worthy of observation, however, that as the sheets of tissue are not sensitive to light they may be dried in any open and warm room, under which circumstances thorough desiccation occurs in, at the most, two or three days; any dust adhering during the drying is of little consequence, as that surface of the film is washed away in development.

Next week the sensitising and subsequent operations involved in the formation of the relief will be dealt with.

DARK ROOM ILLUMINATION.

In continuation of the subject of dark room illumination: the method I propose is based upon an assumption that it is vain to attempt finding a light that has no action on a gelatine film. What is wanted, and what I think is ultimately to be found, is a light-giving material which will impart the highest proportion of sight-giving power as compared with its action on a sensitive plate. In searching after such a light we are not pursuing a shadow, but something capable of being found and utilised.

Looking at the matter theoretically, there must be some part of the solar spectrum which gives out light having the property mentioned; that is, the highest possible sight-giving power as compared with its power of acting on a gelatine plate. That being so, there are two things to be done:—

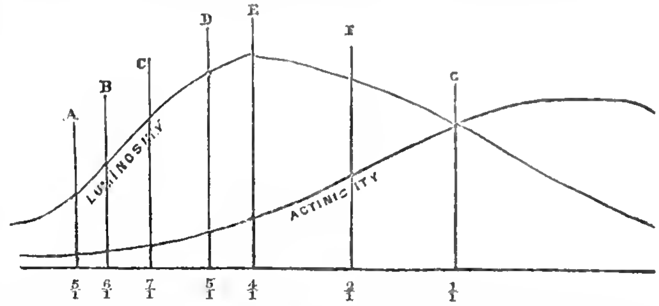
1. To find the position on the spectrum where this is true.
2. To find a material or combination of materials which will give a light nearly approaching the tint already found.

Now these two proportions may, to some, look very like two propositions—1st., to find a fortune; 2nd., to find the best way of keeping the same! But to me the first two propositions are infinitely easier of solution than the second.

The great difference of opinion as to lighting, and the greater difference in the various shades employed by photographers, show that the subject is one which has never been thoroughly investigated on a scientific basis, or at least that no authoritative fiat has gone forth sufficiently powerful to convert the majority.

The way I propose to set to work is to erect two curves—one representing the luminosity or lighting power of the spectrum; the other the actinicity or plate-acting power of the spectrum. Having done so, the point having the greatest proportional lighting power is easily found by a little measurement and calculation.

It will be seen that, although the luminosity is greatest at E, the proportion of luminosity to actinicity is only $\frac{4}{1}$, while at C, although



the luminosity is much lower absolutely, the proportion is $\frac{7}{1}$. At no other part in the spectrum is the proportion so high, and, therefore, this part of the spectrum will give the greatest amount of light compared to its action on a sensitive plate.

What remains to be done is to find a medium answering to the colour of the spectrum at the point C; and this may be effected by passing a number of pieces of glass or other material, supplemented with paper if necessary, in front of the spectroscope, observing when there is a near approximation to the tint wanted.

The only other way that I know of arriving at the same result is the lengthy process of actually trying the various light-giving media and their action on gelatine plates—a kind of "survival of the fittest" process, somewhat akin to that of a man marching over a field and knocking his toes against all the stones to find out which is the hardest.

From two curves which I have erected, and which I think are nearly correct, I make out the tint required to be identical, or nearly so, with the β or orange line in the lithium spectrum.

G. D. Macdougald.

ON THE VALUE OF DIAPHRAGMS IN PHOTOGRAPHIC LENSES.

[A communication to the Photographic Society of Ireland.]

Most amateurs on commencing landscape work are troubled by the various stops which are supplied to the lens they possess not bearing any definite relation to the full aperture of the lens, so that, even if they know the rule to square the exposure for each decrease in size of the stop, they are still in trouble on account of the numbers on them not having any definite relation; and, further, if they try to employ another lens after having got used to their own they are rather worse off than before—for a time, at least. All photographers know that different lenses possess different rapidities; but yet this difference is more apparent than real, the whole difference lying in the stops.

In order to define accurately the size of a diaphragm used in any lens a formula is usually given for it, it being generally written as an italic "*f*" divided by some number; for example, $\frac{f}{10}$. This simply means—assuming that *f* means "focus"—the length of the focus of the lens divided by some figure that will give the size of the stop. Thus, if we have a lens of eight inches focus, and find by measurement that the largest stop be half-an-inch, on dividing the latter into the former we get sixteen as a result. Now write this as $\frac{f}{16}$, and we have the exact relation of the stop to the focal length. If another stop measure one quarter inch, the resulting fraction will stand $\frac{f}{32}$. By this simple means we see at once that the latter stop is one-half the size of the former, and that it will require four times the exposure.

Again: should it be necessary to have two different lenses in use, as it may not always be possible to have them of the same class—a short-focus symmetrical and a long-focus single landscape lens, for example—some means of comparing the rates of exposure should be at hand. In two such lenses at present in my possession I find that the full aperture of the single lens is $\frac{f}{10}$, while that of the symmetrical is $\frac{f}{8}$. On squaring these the relation stands pretty near as one is to one and a-half, so the latter lens requires an increase of exposure in that ratio. From this we see that all lenses possess the same rapidity, *provided the stop bear the same relation to the focus*—the great difference in the rapid lenses over the slow ones being that they can work with much larger aperture.

In order to equalise the various makers' lenses the Photographic Society of Great Britain have recommended what is termed a "uniform system" of numbering the stops. They recommended that all stops having the formula $\frac{f}{4}$ be stamped with the figure 1—this being the largest aperture that it is at present possible to make

—and every other stop with that number which would indicate the exposure in comparison with the standard $\frac{f}{4}$, without regard to whether all the stops can be found in the lens or not.

The figures would run thus :—

$\frac{f}{4}$	$\frac{f}{5\cdot6}$	$\frac{f}{8}$	$\frac{f}{11\cdot3}$	$\frac{f}{16}$	$\frac{f}{22\cdot6}$	$\frac{f}{32}$	$\frac{f}{45}$	$\frac{f}{64}$
1	2	4	8	16	32	64	128	256

The intermediate ones can be calculated in proportion. If this were carried out by all makers, no matter what lens we take up the exact rapidity can be seen at a glance.

To those of my readers who prefer comfort in the field to a little trouble I would strongly recommend a slight modification of the above. I have tried it for the past summer and found it of great help:—

Firstly: Calculate the formula of the various stops in the lens. Select three or four of them that bear a direct proportion to each other, so that the exposure may be—say, the middle stop—four times the full aperture, and the small one four times the middle, consequently sixteen times the full aperture.

Secondly: Calculate from the table of *Comparative Exposures*, compiled by Mr. W. K. Burton, in THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC, page 259, and carry it to the field. I have mine pasted round the focussing-glass. If every exposure be given in accordance with that list, and a note of each exposure be kept at the same time, much may be done in getting accurate ideas of dull and cloudy weather, &c.

The following are a couple of lines from the above table for the average full apertures of the rapid rectilinear and portable symmetrical lenses :—

	Sea and Sky.	Open Landscape.	Landscape with Heavy Foliage Foreground.	Under Trees.	Fairly Lighted Interiors.	Badly Lighted Interiors.	Portrait in Diffused Light out of doors.	Portrait in Good Studio Light.	Portrait in Ordinary Room.
	Sec.	Sec.	Sec.	Sec.	Sec.	Min.	Sec.	Sec.	Sec.
$\frac{f}{8}$	$\frac{1}{40}$	$\frac{1}{12}$	$\frac{1}{2}$	40	40	8	$\frac{2}{3}$	4	16
				M. Sec.	M. Sec.				
$\frac{f}{16}$	$\frac{1}{10}$	$\frac{1}{3}$	2	2 40	2 40	32	$2\frac{2}{3}$	16	64

As an addendum to the above I may add some of the results I found during the past summer and present winter, in the hope that other observers may go on in the same path and check my results. The above figures appear correct for a "ten-times" plate in bright sunlight in summer, between the months of April and September.

In an ordinary dull, cloudy day in summer I found it necessary to double the exposure. After four o'clock p.m. the light gets much worse, so it is necessary to double it then also, even if the sun be shining brightly. After five p.m. treble exposure was given. On a bright, sunny day, this winter, at mid-day, I got good pictures with four times the normal summer exposure.

While I know that many may not agree with me that the above simple rules are any use, yet I cannot help thinking that the fact of having them so tabulated is a great help in practical work; and, even if a little error do creep in, it does not do any harm, as double or half the correct exposure does not make very much difference, a slight modification of the developer making matters right again. Even in cases where I accidentally gave four or five times the correct time the plates were still saved by intensification. I never completely lost a plate from over-exposure unless I gave it from ten to one hundred times the time allowed in Burton's table. This ought to give enough margin for inaccuracies in the figure.

In conclusion: if any present have found different results to the above I am sure they will let me know, as I would be very glad to get as near as possible to the correct figures. JOHN A. SCOTT.

A FEW "TALES OUT OF SCHOOL."

A VISIT northwards early in January would seem to be a little out of place, but when one considers that residents in most of the Scotch towns rusticate for some months in summer, either at the seaside or inland, this fact creates a difficulty as to reaching them, and photographers are generally busy with tourists, so that they have little time for gossip. I visited my namesake, Mr. J. Henderson, of Perth, and enjoyed his hospitality. That gentleman, like myself, has nearly abandoned wet collodion; and, in spite of the want of uniformity in the plates he uses (which is also my own experience), produces splendid work.

A little party of us ran down to Dundee to pay our respects to the great whale. Here a travelling photographer was doing a roaring trade in positives. A chair was placed close to the mouth of the whale, and the open jaws served as a background. One thing I noticed, namely, that his exposures (six to eight seconds) seemed lengthy. Imagine our surprise to find that he was working without any diaphragm, and that the photographs were fearfully over-exposed. A ferrotype plate cut up served to make a stop, and we had the satisfaction of seeing his teeth (the whale's) much sharper.

No complaints as to slackness of trade were made—in fact, all agreed that the last season was "no bad;" but to me it is the credit system that is bad. Photographers have to wait at least twelve months for their money. I noticed that in several cases cash at sitting might have been obtained. I remember having my portrait taken by an Edinburgh photographer some twenty years ago. The photographer sent the *cartes* home to my hotel and left them without the cash, having no idea who I was. I would advise my northern brethren to keep in mind that "a bird in the hand is worth two in the bush."

I heard much to interest me from Mr. Tunny, in Edinburgh, of his American experiences. I saw the wonderful waxed-paper negatives taken upwards of thirty years ago, seemingly as perfect as when newly done—certainly photographically as good as any gelatine negatives taken at the present time.

I had the honour of attending one of the meetings of the Edinburgh Photographic Club, and there was much energy and competition displayed—indeed, second to no other club. Mr. Smith exhibited his bijou camera, and negatives taken with it while in Italy last season. The discussion was principally on a safe light for the dark room. Many lamps were exhibited, and a short, suggestive paper was read by Mr. Jameson on that subject. I was invited by the Chairman, Dr. Thomson, to offer some remarks, but Mr. Tunny quite "took the wind out of my sails" by asking me not to say anything until I had heard all. The wisdom of Mr. Tunny's suggestion I very much question. Mr. Jameson and I are working on the same tack, and I do not object that Mr. James *Sun* should shine above or eclipse Hender *Sun*. All I want is a good, safe light (not yet found). Allow me to say that no light will suit me that will affect the most sensitive bromide of silver, or render luminous a very sensitive sample of phosphorescent sulphide of calcium.

My entertainment socially by the Edinburgh Photographic Club has been so well told in these pages that I need scarcely say more, except that the whole affair took me so much by surprise that I was rendered almost speechless. I heartily thank all for the trouble and considerable expense incurred on my behalf. My wife quite agrees with me that the kind expressions towards herself were merited, but not those bestowed on the writer.

Mr. Marshall Wane's magnificent gallery has, I fancy, been noticed before. That gentleman does not believe in washing his prints very long. At his establishment I saw a large rotary washing machine at work, driven by a water motor. The time employed to wash is about twenty minutes. The water is turned off, and a few turns more by hand suffices to nearly dry the prints. Mr. Wane prefers water power, as it does not neglect the work. Another "dodge" I saw at Mr. Wane's which may be new to several of your readers, namely, a chair for supporting the sitter while taking vignettes. The chair has two backs —one in front of the other. The front one is hinged to the seat, and a quick-acting screw is fastened to this from the back, so that when the sitter is seated one or two turns of the screw brings the back to the sitter. Since my return home I have rigged up one, with this difference—that I have fastened two backs together by a hinge, these backs having a vertical movement, which I think is an advantage.

In Glasgow, as regards the weather, I had my usual luck—that is, when not raining it snowed! But once under the hospitable roof of Mr. George Mason, of Sauchiehall-street, the elements were defied. Anyone visiting Glasgow should call and see his stock of photographic goods. The Glasgow Photographic Society received me with open arms, and added to my vanity by electing me an honorary member.

Visiting the veteran photographer, Mr. James Bowman, who shook me cordially by the hand, and, after a little chat on a subject very interesting to both (the phenomenon called "spiritualism"), I was invited to look round and see if there was anything novel. One thing worth mentioning is a negative drying-frame. It is a copper box twenty-four inches high, twenty inches wide, and two inches deep. Across this are several laths (adjustable) to rest the plates on. At one end, about midway, a pipe is attached to a small boiler over a Bunsen burner. By regulating the supply of gas any temperature may be kept up uniformly. At one of the lower corners is a small outlet to allow the condensed vapour to escape, and I saw a vessel placed to catch the distilled water. I think a good name for this apparatus would be "a double-distilled negative drier." Mr. Bowman has a convenient arrangement in his printing rooms—four or five large tables, each about seven feet by five, lathed across to support the printing-frames. The tops of these tables are swung on pivots like a table mirror, so that they may be inclined at any angle in fine weather. The printing is done in the open air, and, on a shower approaching, the tables, being on wheels, are moved under glass.

My next visit was to Mr. John Stuart, of Glasgow, and Provost of Helensburgh. There I saw his superb new studio, beautifully fitted, and almost indescribable. His backgrounds were particularly noticeable. If all the backgrounds that I have seen (some miles) bearing Seavey's name are genuine, he must already have considerably overdrawn Rubens. Photographers get good commissions here. Fancy an order for some hundreds of large carbon pictures about four feet by three! All the printing is done at Mr. Stuart's Helensburgh studio. I observed that, although the day was sleety and wet, no moisture seemed to get into the glass-room. This was explained by the fact that the glass was bedded-in only, no putty being used outside. The edges of the glass and bars are well painted, and, while the paint is tacky, powdered mastic is dusted on. Mr. Stuart's experience of this method extends over some years. Half-a-day's sail on the Gareloch, accompanied by Mr. and Mrs. Stuart, convinced me that many pretty "bits," especially the snow-tipped mountains, could be secured even in bleak January.

I fancy my little account has got somewhat "mixed." If I have not given credit to whom credit is due, I beg they will not blame me but my memory and the want of a note-book. Thus ended a very pleasant trip. I would strongly recommend photographers who cannot spare time in summer to run north in winter. They will not experience any trade jealousies, and always find something to learn.

A. L. Henderson.

COPYRIGHT LAW IN BRIEF.

Copyright means the sole and exclusive right to copy, reproduce, and multiply, by any means and in any manner, any original painting, drawing, photograph, or other work of art.

Copyright accrues to the *author* of a work of art by virtue of authorship, and lasts for his or her natural life, and seven years after death.

As soon as the copyright in any work is registered in accordance with the provisions of the Act of Parliament known as Vic. 25 and 26, cap. 68, it becomes personal estate, and can be sold, assigned, or demised, just the same as any other personal estate.

A properly-registered copyright will enable the owner to take proceedings and recover penalties against anyone who, without permission, copies or imitates, wholly or partially, the whole or any portion of the orfginal work of art to which such copyright applies.

Under the Copyright Act an original negative, or the photographic copy of it, is considered a work of art.

A photographer can make a negative of a landscape, of natural objects, of architecture—in short, of any object or objects in which there is no copyright—and the correct registration according to the Act will secure to him his copyright in that particular negative or photograph. He cannot, however, prevent any other person making another negative of the same objects, even from the same point of view, and as nearly as possible under the same circumstances.

If a photographer take the portrait of a person of eminence—a member of the Royal Family, musician, actor, &c., &c.—copyright can only be secured by a signed agreement, made at or before the time of sitting, between the person whose portrait is made and the person who makes the negative. If this be not done, and the names of the parties to the agreement properly filled up in the registration form, there will be no copyright.

If a *group* of persons be taken, it will be necessary to have the signature of every member of the group to the agreement.

Seeing that copyright accrues only to the *author* of the work, a principal cannot send out his operator to execute his commission and then take the copyright to himself; it will, in every case, accrue to the author of the work.

In the present state of the law it would seem to be absolutely necessary that where a principal does not himself execute the work, or have it done under his personal direction and supervision, he must have an assignment of the copyright from the person he employs, and who, in the eye of the law, is the true author.

Portraits taken in the ordinary way of business have no copyright, except by special agreement; but that does not give the right to the photographer to print from the negative for his own purposes. He is bound to use the negative, if he retain it, only to the order of his employer.

The owner of a copright picture cannot have it reproduced or copied unless he *also* possesses the copyright.

Authors of original works should secure copyright by registration as early as possible; illicit copying of an original work before the copyright is registered is actionable, and confers no copyright.

In transfers of photographic businesses each copyright negative must be duly assigned, and the assignment registered at Stationers' Hall. Unless this is done the purchaser of the business does not acquire the copyrights.

Proper copyright forms can be obtained for one penny each at Stationers' Hall.

The penalties for infringement are very heavy, the offender upon conviction being liable to be adjudged to forfeit a sum not exceeding ten pounds for each copy sold or offered for sale.—*Autotype Notes.*

SOCIETY OF ARTS.

At Mr. T. Bolas's third lecture at the Society of Arts on Monday evening last, the 11th instant, which was the concluding one of the series, the chair, as on the two previous occasions, was occupied by Mr. B. F. Cobb, Vice-President of the Society.

Mr Bolas, referring to the anastatic process, submitted for examination some prints obtained by a recent modification of this process. Whereas in the anastatic system, as originally practised, an affinity was established between the dried-up ink of any printed matter and fresh transfer ink applied by careful friction with a roller, in the new modification the transfer ink was applied in a fluid form, adhering only to the printed portion, and not to the paper. This was then transferred to a lithographic stone or zinc plate, and impressions obtained by the usual process of lithographic printing, or, if desired, by converting the plate into a phototypic surface.

Long previous to the introduction of photography, mechanical appliances had been introdued to effect the conversion of objects in relief into lines adapted for the requirements of the engraver or etcher. Colour printing had also been applied to photolithography, and the lecturer directed attention to some excellent examples of this class of work by Mr. William Griggs, of Peckham, which were suspended on the walls.

Alluding to the prospective importance of phototypic over photolithographic processes, he (Mr. Bolas) said that any process whatever which could yield an impression in fatty ink was applicable for either of those two methods of printing, owing to the facilities which now existed for forming a raised typographic surface. Concerning intaglio or cavity printing from photographic sources, it was now only very little practised on a commercial scale. In 1859, Her Pretsch established works at Holloway for the purpose of practising this method of printing, the process employed being his own invention; but the photogalvanographic system was introduced before its time—the world was not ready to receive it.

Various applications of the stannotype process of Mr. W. B. Woodbury to the production of printing surfaces were referred to, and some of these were illustrated in operation. A stannotype plate having been inked was pressed in contact with a grained sheet of paper and an image in transfer ink obtained as the result. This image could be either positive or negative according to the nature of the stannotype original. In the course of various experiments a print in fatty ink was transferred to a wood block and handed round for inspection.

Two plates produced by Niepce in 1827 were submitted for examination, and were inspected with great interest. Niepce's process consisted in coating a plate of metal with bitumen and then subjecting it to light, by which certain portions were rendered insoluble. It was stated that surface blocks produced through the agency of bichromated albumen were now coming into general use.

The Goupil process of *photogravure* was next introduced, and it was stated that, while the precise method adopted was retained as a secret, there was every reason to believe that it was one closely allied to a process published several years ago by Mr. Woodbury, in which a grain was obtained by the mixture of a gritty powder with the gelatine of which the relief was composed, this being afterwards embedded in a metallic plate by pressure. Several excellent and suggestive specimens by Mr. Woodbury, executed at an incipient stage of the process, were exhibited.

The Waterhouse grained process was of a somewhat similar character to those just mentioned. The grain in this case was obtained by sifting fine sand upon a gelatine image while still soft, and brushing it off when quite dry, by which the surface was left in a granulated state. A specimen was exhibited.

Specimens of a grained process by the Autotype Company were shown, attention being directed to the affinity that, to judge by their similarity, seemed to exist between the latter process and that of Waterhouse.

Another process, concerning which no intimation of its nature had been published, was one by which Mr. Alfred Dawson had reproduced, with great excellence, a copy of an indian-ink drawing.

Mention was made, but no specimens exhibited, of a process of etching by Obernetter, in which an image formed of chloride of silver in a gelatine film was pressed in contact with a smooth plate of copper, the action resulting in the formation of chloride of copper in the metallic plate, which salt on being removed left the image etched.

Several applications of photographic printing to pottery and general ceramic work for burning-in were referred to; among others, some by Mr. Duncan Dallas. Several specimens of work in printers' ink by this gentleman were exhibited, including some of the first ever executed by him, and thus possessing historical value; also several examples of Dallastint copperplate work applied to pottery decoration, bearing dates 1863-65. One of these, burnt in by Copeland, of Stoke-upon-Trent, was stated to be the first application of a photographically-engraved plate to the ornamentation of pottery done in this country. Examples of Dallastint surface-block work applied to pottery were also shown; and we may here remark that at the close of the proceedings a *plaque*, upon which a photograph had been printed in ceramic "ink" five years ago by Mr. Dallas, and which had remained unburnt since that period, was fired in a gas furnace upon the table, with a perfectly-successful result, although kept so long.

In speaking of the applications of collotype printing, Mr. Bolas said it was almost incredible at what a low price these pictures were produced on the continent. As an example of this he exhibited two match-boxes full of wax vestas, and each adorned with a pretty and really creditable collotypic photograph, respectively, of *Cologne Cathedral* and a *View of Naples*, the two being purchased retail for one penny. With respect to this process he observed that the water-glass substratum of Husnik was now quite superseding the old-fashioned substratum formed by coating with thin albumenised gelatine and then exposing it to light. The specimens of collotype printing exhibited by the Autotype Company were, he thought, as fine as anything that could be produced.

At the close of Mr. Bolas's lecture, the CHAIRMAN offered the thanks of the members to that gentleman, and expressed the great pleasure it had afforded them to listen to such a series of practical lectures, in which so much matter had been compressed into a small space. This was seconded, and carried by acclamation.

NOTICE TO PROCEED.

No. 5,947.—"Improvements in the Preparation of Photographs and Treatment of Drawings or Designs Printed upon Paper for the Purpose of Imitating Stained or Embossed Glass." GEO. RYDILL.—*Dated December* 31, 1883.

PATENT SEALED, FEBRUARY 8, 1884.

No. 3,948.—"Improvements in the Manufacture of Pliable Plates as a Substitute for Glass for Photographic Purposes." J. J. SACHS.—*Dated August* 14, 1883.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
February 19....	Bolton Club..................	Studio of the Club, Chancery-lane.
,, 20....	Photographic Club	Anderton's Hotel, Fleet-street.
,, 21....	London and Provincial	Mason's Hall, Basinghall-street.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

THE annual meeting of this Society was held at 5A, Pall Mall East, on Tuesday evening last, the 12th instant,—Mr. James Glaisher, F.R.S., President, in the chair.

The minutes of the last meeting having been read and confirmed, the following gentlemen were elected members of the Society:—Messrs. J. Desiré England, Norman May, John Henry Knight, and Robert S. Kidd.

The ASSISTANT SECRETARY then read the Council's report for the session 1883:—

The Council observed that during the year 1882 great mental activity had been exhibited in investigating the chemical relations of dry-plate photography. This activity had been followed by some reaction in the year 1883. There was now comparative rest; for, although it could not be claimed that the reactions were thoroughly understood, yet the practical results were so fairly uniform that the question had ceased to be a burning one. There had, nevertheless, been great activity during the past year, as would be understood by reference to the list of papers which had been read.

The Council referred with much satisfaction to the completion of the standard for flanges and screws, which had been under consideration in 1882. Actual gauges had been manufactured for the Society by Messrs. Whitworth and Co. and Messrs. Ross and Co., and these standards would be open to all engaged in mechanical photographic work. This marked the end of the year's proceedings.

The subject would receive further consideration at the photographic congress to be held at Brussels, to which delegates would be appointed by the Society.

It having been considered desirable to have an optical lantern, the Society had had two made—one, by Dallmeyer, for the oxyhydrogen light, and the other for oil. These formed part of the property of the Society, and, it was hoped, would assist in many investigations of photographic problems. Already on two occasions they had rendered good service. They had also been most successfully used at the evening meetings during the last exhibition.

The value of the technical meetings continued to be evident, the most regular attendants being gentlemen known as skilful observers; and it was to be noted that knowledge was freely communicated by them. Sometimes original ideas were brought forward. It was a notable feature of these meetings that the proceedings need not be confined to those present; country members could join in discussion by letter.

The exhibition of 1883 afforded very clear evidence that the introduction of gelatine plates into every branch of photographic work is an accomplished fact, and is one not to be regretted. The work had reached a high average of excellence, nothing fine having been done in collodion. Many considered that the last exhibition had been the finest held by the Society. A promise was held out of new work still better. No doubt the exceeding rapidity of exposure, enabling high artistic merit to be introduced, was the chief feature of the last exhibition. The success of the Monday evening lantern meetings had been very great, and the increasing interest in the matter was shown by the fact that the attendance had increased from 97 on the first night to 777 on the last. The Council would consider the advisability of setting aside more than one evening of each week for lantern work next year. The constitution of the jury for deciding awards had been altered, no painters being upon it this year. Very full statistics of the exhibition were then given, showing that the number of exhibitors, of pictures, and of visitors had increased since past years. There had been so much application for space that it had been found necessary to reject many pictures, and it was expected that still more would have to be rejected next year, whereby the standard of excellence would probably be raised.

Presentation prints had been sent to every member of the Society. The Progress Medal of the Society had been presented to Dr. Eder.

It was regretted that the Secretary, Mr. F. Maxwell Lyte, had had to retire on account of ill-health.

The Society had sustained the loss of six members by death, and five had retired. The membership had been increased by forty-two, making a total of 363 members—a greater number than the Society had possessed for many years.

The Council hoped, in conclusion, that the future would continue to reveal more of those discoveries which might be said to lie dormant in the minds of members.

Mr. C. RAY WOODS proposed that the report be received, adopted, and printed in the usual way. He praised the manner in which the Council had laid the report before the meeting.

Mr. JOHN SPILLER seconded the motion, which was carried unanimously.

The TREASURER then read his report for the past year. The income of the Society had considerably increased, and, although the expenditure had also increased, and, indeed, had been during the past year in excess of the income, there was still a large balance in hand. The extra expenditure was more than accounted for by property in the possession of the Society.

Mr. T. SEBASTIAN DAVIS moved the adoption of the report. He congratulated the Society on the manner in which the extra expenditure had been incurred, whereby it had become possessed of the standards and lanterns already referred to.

Mr. G. L. ADDENBROOKE, as one of the auditors, seconded the motion, and mentioned how easy the audit had been rendered by the excellent order in which all the accounts had been found.

The vote of thanks was carried.

The CHAIRMAN said that, considering the report that had been read, they ought to be very gratified to their Treasurer for having not only done his work so well, but for having been so zealous in the interests of the Society. He also referred to the fact that although there had been more additional work to do, and although the editor had been unwell for a great part of the year, the editorial expenses had been diminished by £14. He therefore asked for a hearty vote thanks for Captain Abney.

The vote of thanks having been passed,

The CHAIRMAN asked that a vote of thanks be given to the auditors, and afterwards to the scrutineers of the votes. Both were carried.

The Progress Medal was then handed by the Chairman to the Treasurer for transmission to Dr. Eder, as a reward for his investigations in gelatino-chloride plates. He briefly recapitulated the useful work which had been done by Dr. Eder during the past few years.

The scrutineers having by this time counted the votes, the new officers were announced as follows:—*President:* Mr. James Glaisher.—*Vice-President:* Colonel H. Stuart Wortley.—*Treasurer:* Mr. W. S. Bird.—*Council:* Captain Abney, Messrs. F. Bedford, T. Bolas, Professor W. F. Donkin, Messrs. Jabez Hughes, W. B. Bolton, and W. England.

Colonel WORTLEY rose to propose a vote of thanks to the President. He considered that a great portion of the success of the Society was due to the exertions of their President, who managed to give a great portion of his time to the work in spite of his being such a busy man. He hoped that he (the President) would continue to rule over the Society for very many years.

Mr. SPILLER seconded the vote of thanks, which was carried by acclamation.

The CHAIRMAN, in reply, said that on looking back to the time, thirty-five years ago, when he had worked at photography, he thought he must be becoming a very old man. Nevertheless, he would continue to exert himself for the Society so long as it was asked of him and he was capable of work.

Mr. W. F. DONKIN was announced as Honorary Secretary in place of Mr. F. Maxwell Lyte whose prolonged illness compels him to resign the post.

Mr. W. E. DEBENHAM wished to call the attention of the Society to a matter which might be of considerable importance—that was to the changes which might be made in papers read before the Society and afterwards printed in the *Transactions.* He referred particularly to a paper read by Captain Abney in June last. He said that certain statements with regard to the effect of pressure on sensitive films were made in the paper as read; that such statements were criticised afterwards, an error being pointed out, and that advantage was taken of the criticism, the subject matter of the paper being materially altered in the report of the proceedings of the Society. He (Mr. Debenham) read various letters which had passed between himself and the Council of the Society. He put forward various arguments in support of the correctness of his statements, and proposed a motion as follows:—"That this Society disapproves of any material alteration being made in papers after these have been read before it, and before their being published in its *Journal.*"

Mr. W. M. ASHMAN seconded the motion.

Mr. T. SEBASTIAN DAVIS proposed an amendment to the effect that the motion was unnecessary.

The amendment was carried by a large majority, and the meeting was then adjourned till the 11th March.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held in the room of the Society of Arts, John-street, Adelphi,—the chair being occupied by the Rev. F. F. Statham, M.A., President.

It was announced that the committee had decided that the subjects for competition, instead of being sent in monthly as heretofore, might be sent in at any time before the end of the session, when they would all be judged together.

Mr. F. A. BRIDGE then read a paper on the subject of *Willesden Paper.* He began by saying that he was not in any way interested in Willesden paper from a pecuniary point of view, but that he brought it forward merely with the idea that it might be useful to photographers in several ways. The paper might already be known to many present, as it had been extensively used at the Fisheries Exhibition. The Willesden paper was paper of various kinds treated with a bath of copper and ammonia. This renders the paper waterproof and rot proof—he had almost said thief proof. One ply of paper might not be absolutely waterproof, inasmuch as there might be small accidental pinholes in it, but by having two or more plies the danger of this was avoided. When the paper was cemented together in layers with the Willesden composition it might be boiled, and still would not separate. It had struck Mr. Bridge that a temporary, or even permanent, dark room might be made out of the paper. Mr. Healey, the manager of the Willesden Company, had been good enough to construct a portable dark room, which was fitted upon the platform. He (Mr. Bridge) had seen buildings made of the paper which had been standing long exposed to the weather. A vessel constructed of the material was shown full of water to exhibit its water-tight properties. To photographic printers the paper would be useful. On a shower of rain coming on the frames could be covered with a piece of Willesden paper. For amateurs, who often found that a dark room indoors was considered to interfere with domestic arrangements, the paper would be unfit. They might put up a dark room, for example, at the bottom of the garden. The backing of pictures was suggested as a possible use of the paper. It was also thought that it might be useful for packing dry plates in. It appeared particularly suitable for developing dishes. He (Mr. Bridge) made a dish out of a piece of the paper to show how easily it was done. The corners were fixed up with marine glue. He had developed a plate in such a dish that day, and the chemicals appeared to have no effect upon it; but, if there were any doubt, it was most easy to cover the paper with plain, colourless varnish or india-rubber in benzole. Samples of the paper so coated were shown. Hyposulphite of soda had a bleaching effect on the paper if it were unprotected, but appeared to have no further action. He (Mr. Bridge) had seen a drain or water-pipe made of the material. The pipe had been in use for a long time, and this proved the durability of the material. A set of pieces of Willesden paper and Willesden paper cemented with Willesden composition to canvas was placed in boiling water. Beside it was placed in a set of pieces of ordinary paper and paper shred to canvas—a portion of a registered envelope, in fact. The latter were all reduced to pulp, whilst the former were unchanged. Some lantern blocks made of the paper were shown.

The CHAIRMAN said that, although the subject was not a strictly photographic one, it was one which was most suggestive, in showing how many ingenious inventions were indirectly applicable to photographic work. Mr. Bridge had pointed out several uses to which the paper might be applied. There were, doubtless, many others. For example: the temporary repairing of roofs; also for the packing of apparatus. Mr. Warnerke had recently told of the destruction of a quantity of his apparatus on board ship by wet. By the use of Willesden paper this might have been avoided He suggested that by its means hay and corn might be protected from the weather, and thereby often saved.

Mr. HEALEY handed up a photograph showing that the paper had already been used for this purpose. The covering complete for a large stack would cost £18.

Mr. W. M. ASHMAN asked if that material could not be *welded* into developing duties.

Mr. HEALEY said the difficulty was to get a perfectly waterproof glue. The Willesden Company had a glue which was perfectly satisfactory when applied with the necessary skill, but he did not know whether the general public would be able to use it.

Mr. KEEN said that the Willesden canvas made excellent backgrounds where no great width was necessary.

Mr. MACKIE asked if a thick board of *papier-maché* could be impregnated with the composition.

Mr. HEALEY said it could not. It was necessary to put a layer of the composition between each two thicknesses of the paper.

Mr. WILLIAM BROOKS, referring to some Willesden writing paper which had been shown, suggested that if such could be produced without lines it would make a good support for collodion emulsion.

Mr. HOWARD mentioned the difficulty that amateurs often had in getting a room really dark, and particularly in having a means of getting in and out of the dark room without letting in a flood of white light. He said that by means of Willesden paper they might, so to speak, have a dark room within a dark room.

Mr. HARRISON said that the paper might be used for many odd-and-end purposes.

The PRESIDENT suggested water pipes, amongst others.

Mr. BRIDGE mentioned that canvas and ropes were treated with the composition; they thus became waterproof without the weight which tarred ropes had.

Mr. HEALEY said that ferrocyanide of potassium might be used as a test to discover whether so-called Willesden paper was genuine or not. If it were, the ferrocyanide turned the paper dark brown.

The CHAIRMAN proposed a vote of thanks to Mr. Bridge for his papers.

Mr. BRIDGE said that, as by far the greatest part of the trouble had fallen on Mr. Healey's shoulders, he would transfer the vote of thanks to him.

Some canary medium was distributed by Mr. Bridge.

Several prints on "enamel paper" were shown. They were considered very satisfactory.

A question was read from the question-box, asking if ready-sensitised paper gave prints more or less permanent than ordinary paper did.

Mr. A. COWAN said there had not been time enough as yet to find out.

Mr. BROOKS confirmed this, but said he had found one point in which ready-sensitised paper failed. After the lapse of sometimes months a lemon stain would appear on the paper.

Mr. F. HOWARD remarked that the permanency or otherwise of the print depended much on the strength of the negative. A strong negative always gave a more permanent print than a weak one.

Mr. E. W. FOXLEE corroborated this. He had prints twenty-five years' old as good as at first, but they were only such as had been got from strong negatives.

Mr. W. M. AYRES showed a number of prints from twenty to twenty-five years' old, which had been done on paper sensitised with a sixty-grain bath, and had been toned on a mixed hyposulphite of soda and gold bath. They were as good as new.

The subjects for the competition were then balloted for. They were read out as follows:—Landscape: *A Shady Nook, A Country View, Enchanting, A Church with Ivy, A Study of Leaves, Clouds and Trees, A Water Trough and Horses, A River Scene, Hay-Making, A Lake with Swans or Water Fowl, A Roadside Inn, A Village.* Figure: *The Shepherd, Afflicted, Happiness, Unearthing a Treasure, Indecision, Mother and Child, Wrath, Rustics, Gone, Dejected.*

The pictures representing these subjects were to be sent in any time before December next.

The meeting was then adjourned.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Society, held on the 7th inst., Mr. A. L. Henderson occupied the chair.

Mr. J. B. B. WELLINGTON showed two plates from same emulsion—one developed with ferrous oxalate and one with pyro., both of them having decided green fog.

The CHAIRMAN thought there might be excess of silver in the emulsion to cause such a decided manifestation of green fog under both developers.

Mr. WELLINGTON replied that the emulsion was made after the formula given by him a fortnight earlier. In mixing it, however, the nitrate of silver had been added to the gelatine solution before being converted into citrate, the citrate of ammonium and liquid ammonia being afterwards added.

Mr. W. E. DEBENHAM thought that this might account for the different behaviour of the emulsion, as in gelatine solution the conversion into citrate would be slow, and probably not complete when the bromide was added.

Mr. F. W. HART showed some celluloid dishes similar to those that he had exhibited before, with the exception that one of these was of transparent instead of opaque material.

Mr. W. H. PRESTWICH thought that this change made them perfect.

A question from the box was read:—"Are albumen prints made upon citro-chloride of silver more permanent than upon the usual chloride paper?"

The CHAIRMAN was inclined to think that they were, and that prints upon the commercial ready-sensitised paper, which, it was understood, contained a considerable amount of citrate of silver, would prove more permanent than those made upon ordinary albumenised paper.

Mr. DEBENHAM said that he could see no reason why the silver reduced by light from citrate of silver should resist destructive agencies more than that reduced from chloride, and he thought that some reason should be given before such an idea could be accepted. Then, too, it was probable that more chloride was reduced than citrate in the papers prepared with the combined salts.

The CHAIRMAN said that another question arose relating to the permanency of silver prints—whether burnishing tended to preserve these or not? He thought that it did.

Mr. J. J. BRIGINSHAW asked whether any member could tell him a ready method of ascertaining the strength of a bichromate bath. He had an old one on which he had sensitised some carbon tissue, and wished to know how to find its strength. He would also inquire whether an old bath was fit to use, as he had understood that it should be freshly prepared.

Mr. A. HADDON said that the readiest way of ascertaining the strength was to evaporate a small quantity—say half-an-ounce—to dryness and weigh the residue.

Mr. DEBENHAM did not think that it mattered if the bath was old in point of time, but that it should not have been much used.

M. BRIGINSHAW replied that the bath in question gave results that he could not distinguish from those furnished by a new one. The bath had been made for more than a year, but had been very little used.

Another question was read:—"Is there no method of coating paper with emulsion, so that after exposure the film may be stripped?"

The CHAIRMAN suggested that paper should be prepared with a varnish the solvent of which is alcohol, and, after finishing the negative, wetting with alcohol should allow the paper to be removed.

Mr. J. BARKER thought that the paper should first be converted into parchment paper and then covered with French chalk. If some of this powder were left thick upon the paper it would not have an injurious effect upon the emulsion.

Mr. JAMES BURGESS had used some plates that had been polished with French chalk. On some of them the powder had been carelessly left, but it had not injured the emulsion.

Mr. HADDON said that Mr. Morgan, of Messrs. Morgan and Kidd, had promised to give a demonstration before the Society of the development of gelatino-bromide opals and of gelatino-chloride paper.

Mr. BURGESS inquired whether there was any advantage in fuming with ammonia the paper sold ready sensitised.

The CHAIRMAN thought that there was, and that that paper could scarcely be fumed too long. In answer to an inquiry, he (the Chairman) said that his fuming box measured twenty-four inches by twenty, and was sixteen inches deep. A saucer of ammonia stood at the bottom, and at a few inches from the top was stretched a piece of fishing net. Two sheets of paper were laid back to back on this net, and left for from three to four minutes. The lid was lined with felt to make the joints tight.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

THE Board of Management held its usual monthly meeting at 181, Aldersgate-street, on Wednesday, the 6th instant.

The minutes of the previous meeting having been read and confirmed, Mr. L. W. Green (Peckham) and Mr. M. A. Wood (New Southgate) were elected members of the Association.

Mr. W. M. ASHMAN submitted some proposed alterations in the rules, which were discussed. It was decided that the meeting of the Board on the 5th of March should be special, in accordance with rule 18.

The other business having been disposed of, the meeting terminated.

PHOTOGRAPHIC SOCIETY OF IRELAND.

THE usual monthly meeting of this Society was held in the Royal College of Science, Stephen's Green E., on Friday, the 8th instant,—Mr. J. H. Woodworth in the chair.

The minutes of the previous meeting having been read and confirmed, Mr. Samuel Boyd was elected a member. Messrs. J. Robinson and R. Brown were proposed for membership, and will be balloted for at the next meeting.

The CHAIRMAN then called on Dr. Scott for his communication *On the Value of Diaphragms in Photographic Lenses.* [See page 103.]

There was a very well-sustained debate on the paper, some of the members having found the system of diaphragms as drawn up by the committee appointed by the Photographic Society of Great Britain of very great value. Owing to the courtesy of Dr. Scott, who had prepared a table showing the relative value of the stops and the exposures necessary to obtain good pictures, Mr. C. W. Watson was enabled to compare this table with the actual exposures made during a tour in Wales last summer, and on only one occasion was there any difference between his note-book and the table.

Mr. GREENWOOD PIM, as also Mr. E. P. JOHNSON, exhibited a collection of lantern transparencies produced on gelatino-albumen plates. The difference between these plates and the ordinary gelatine plates was very marked, the former being much the best for this purpose. Mr. Pim also exhibited some further results he had obtained on eosine plates.

Mr. JOHNSON and Mr. WOODWARD also showed some specimens of enlarging, made on Messrs. Goodall and Steven's paper, which was very good.

Mr. J. V. Robinson passed round a *carte-de-visite* portrait which had been taken in an ordinary sitting-room at night, the subject having been lighted by two ordinary gas jets. The exposure was about fourteen seconds.

The next ordinary meeting will be held on Friday, 14th March.

DUNDEE AND EAST OF SCOTLAND PHOTOGRAPHIC ASSOCIATION.

The fifth ordinary meeting of this Society for the session was held on Thursday, the 7th inst., in Lamb's Hotel, Dundee, when there were about thirty members present. Mr. W. D. Valentine occupied the chair.

The minutes of the previous meeting having been read and approved of, it was arranged that the subject for the next monthly competition be—*Portrait Tak·n in Room.* Four new members were admitted, and one new application was handed in. The routine business having thus been disposed of,

The Chairman called upon Dr. Tulloch to read his paper on the *Shortcomings of Photography.* [Up to the time of going to press Dr. Tulloch's paper had not reached us.] A very animated discussion then took place.

The Chairman led off with the remark that it was not fair to institute a comparison, as Dr. Tulloch had done, between an engraving and a photograph, as the latter was printed on rough paper or in platinotype, and he also said that the widespread use of highly-albumenised paper for large pictures had done much towards preventing the artistic development of photography. He (the Chairman) remarked that the greater intensity of the shadows at the edges was in great measure due to the use of wide-angle lenses.

Mr. G. D. Macdougald said he was of opinion that the too great intensity of the shadows could be remedied by a full exposure. Dr. Tulloch stated that in a picture there should only be one point of pure black, whereas in a photograph there were dozens of such points.

The Chairman proposed a hearty vote of thanks to Dr. Tulloch.

Mr. Geddes (Arbroath) then made a few remarks regarding *Halation: its Cause and Cure.* He stated that in the beginning of December he had sent a paper on this subject to The British Journal Photographic Almanac, but it did not appear. He wrote twice to the Editor, and once to the Publisher, asking the reason of its non-appearance, but received no answer. In his (Mr. Geddes's) opinion halation was caused by the space between the back of the plate and the dark slide, and he found that the evil was completely remedied by laying a piece of blackened cardboard on the back of the plate.

The Chairman said he thought this would not be of use unless it was placed in optical contact with the glass.

Mr. Macdougald thought the cause of halation was that the particles of silver bromide dispersed the light through the film, and he also said that single lenses were much less liable to induce it than compound lenses.

Mr. Matheson had got halation in a plate which had even been backed with burnt sienna.

A vote of thanks was passed to Mr. Geddes.

A question was found in the question-box—"Is there any advantage in fuming ready-sensitised paper?"

It was the opinion of the meeting that there was a slight benefit to be derived from this, as it neutralised the acid in the paper and caused it to tone more readily.

The meeting was then adjourned.

COVENTRY AND MIDLAND PHOTOGRAPHIC SOCIETY.

At the ordinary monthly meeting of this Society, on Thursday, the 7th instant, the chair was taken by Mr. William Andrews, President, who called upon Mr. A. E. Rollason (Hon. Secretary) to read a paper on *Exposures by the Oxymagnesium Light.*

Mr. Rollason said that this phase of photography was quite new to him. It had been suggested that if members would bring cameras to the meeting a few exposures might be made. He had made several trials of the light and found it very actinic, although somewhat difficult to manage without proper apparatus. The light was too strong for direct illumination, and required the interposition of a reflecting screen. In this case the light would be much improved if placed in the focus of a large reflector. Reflectors were also required to soften the shadows, which were found to be rather strong.

As several gentlemen who had brought cameras were by this time ready, and the President volunteering to sit for the first trial, preparations were at once made for exposure. Two twenty-ounce gas jars were filled at the pneumatic trough with oxygen gas (kindly given by Mr. T. J. Lloyd). The magnesium wire was bent round a test tube into a spiral form and fastened to the stopper at the top of the jar. The jar was then placed about ten feet from the sitter (slightly to his left) on a camera-stand about four feet high, while the cameras were on the right hand. All being ready the wire was then removed from the jar, lighted, and re-immersed in the oxygen. The exposure was as nearly as possible about eight seconds. The lens was a single landscape lens, nine inches focus, No. 2 U.S. stop. The plate was one of Mr. Baynton's "Coventry" dry plates. This was a failure, on account of the small size of the stop and slowness of the lens.

The next exposure under the same conditions, but with a portrait lens about No. 10 U.S. stop and the same make of plate, was a decided success. The last was a group taken on a Wratten and Wainwright's instantaneous plate, with the portrait lens, same stop, but with two lights burning—one at ten feet and the other at fourteen feet from the group. The exposure was thought to be about twenty seconds, and was also a success.

The plates were developed exactly alike by Mr. M. J. Danks (at the meeting), in a careful and efficient manner, considering the fact that neither the correct exposure nor the rapidity of the plates were known to him.

On the whole the experiment was fairly successful, and several members expressed a wish to try the light again on a future occasion.

After votes of thanks had been passed to Mr. Rollason and Mr. Danks, the meeting terminated about ten o'clock.

SHEFFIELD PHOTOGRAPHIC SOCIETY.

The ordinary monthly meeting of this Society was held in the Masonic Hall on Tuesday, the 5th inst.,—Mr. Councillor S. Firth in the chair. There was a very numerous attendance of members—so much so that it gave rise to some talk respecting a larger room.

It being the first meeting after the exhibition, many interesting matters concerning it formed the subject of conversation; but, owing to the unavoidable incompleteness of the accounts, the presentation of the balance sheet was postponed till the next meeting. It was proposed that each member note down such ideas and suggestions on exhibition arrangements as he may consider serviceable for next year, as it was unanimously decided that there should be then an exhibition.

Mr. W. B. Hatfield proposed that the best thanks of the Society be given to the many gentlemen throughout the country who so kindly contributed to the recent exhibition, thereby enabling the Committee to organise the most interesting and complete exhibition ever held in connection with the Society.

The resolution was unanimously passed.

Mr. J. Taylor proposed, and it was carried unanimously, that a special vote of thanks be accorded to the Rev. H. J. Palmer and the members of the Liverpool Amateur Pho'ographic Association, for their large and interesting contributions to the late exhibition.

The following gentlemen were then proposed for membership and unanimously elected:—Messrs. Johnson, Hibbert, Shields, Mottershaw, and Hayball.

Mr. J. H. Rawson exhibited a negative with some map-like lines indented in the film, which caused much discussion as to the cause.

It was proposed that the members should commence a competition, the subject to form an illustration of a given word, the word to be suggested by the President, and the best pictures to be put in the Society's large album, with full particulars of the method of production. The first show of pictures to take place at the monthly meeting in April, and the word to be "Contentment."

After examining and discussing a number of prints brought by Dr. Morton, Mr. J. H. Dickinson, Mr. Seaman, Mr. Pilley, and others, a very pleasant meeting was brought to a close.

NORTH STAFFORDSHIRE PHOTOGRAPHIC ASSOCIATION.

The monthly meeting of this Society was held on Wednesday, the 6th inst., at the Town Hall, Hanley,—Mr. C. Altieri, Vice-President, occupying the chair.

The minutes of the previous meeting having been read and signed, Messrs. J. Beardmore, W. Woodall, M.P., Inshull, and Taylor were elected members of the Association.

The Chairman, addressing the meeting, apologised for his non-ability to demonstrate the progress of enlarging from negatives upon Messrs. Goodall and Steven's argentic paper, on account of an accident which had lately befallen his condensers, they having been cracked, and the new ones ordered not having come in time for the meeting. He would, however, give the members an invitation to his own laboratory next month, when he should have great pleasure in redeeming his promise. In the meantime he called upon Mr. Allison—who, he was glad to see, had brought some fair-sized negatives—to give a demonstration in printing direct upon this paper.

Mr. W. B. Allison said that having heard a day or two previously of their Chairman's accident, in case it should not have been repaired in time for the meeting he had brought a few negatives and some of Messrs. Goodall and Steven's enamel argentic paper to prevent entire disappointment. The room having been darkened, printing-frames were filled as usual in ordinary silver printing, and, a gas burner being lighted, exposures varying from one to two minutes were given at about four feet from the flame. The resulting pictures were all developed successfully with ferrous oxalate developer, and were greatly admired both for their vigorous depth and the purity of the whites obtained with this paper, the pictures somewhat resembling platinum prints highly glazed.

This simple printing process was much admired, and a vote of thanks was passed to Mr. Allison.

The Chairman handed round a splendid set of about thirty lantern slides, made by contact printing upon bromide plates. The quality of the slides, with perfectly clear glass in the high lights, showed that in careful and skilful hands alkaline pyrogallic development is equal to any other.

A vote of thanks having been passed to the Chairman, the meeting separated.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

This Society met on the 18th January, when the chair was taken by Prof. H. W. Vogel, President, who intimated the death of Mr. J. H. Dallmeyer, and supplemented the intimation by a short account of Mr. Dallmeyer's life and of his services to optical science, dwelling particularly upon his improvement of the photographic lens. The memory of the deceased was honoured in the usual way by the members rising in their places.

In a letter from Milwaukee Dr. Vogel spoke of the photographing by Mr. Falk of the stage of a large theatre in New York by electric light.

In consequence of this Mr. Falk sent him several cabinet-sized copies of these pictures, inquiring, at the same time, whether Dr. Vogel's remark that "the electric light is better in Berlin than in New York" is to be taken to mean that such views can be better taken in Berlin.

The CHAIRMAN explained that he meant the electric lighting of streets, which is much better than in New York, but that they were not yet able to take views equal to Mr. Falk's.

A French correspondent wished for information regarding a newspaper notice he had seen of the directors of the Berlin National Gallery having allowed certain pictures to be reproduced by "photochromography."

Herr MILSTER remarked that what was meant was the lichtdrucks in the chromolithographic style of Herr Frisch, some of whose reproductions of water colours and pastel drawings are so beautiful that one might almost doubt whether the original or the copy was before him.

A provincial member, who intended to build a glass-house, and, owing to local circumstances, could only have a frontage to the east, so that in the forenoon the sun would shine directly into it, asked for advice how best to modify this disadvantage. He was recommended not to build such a studio; but

Herr HALWAS said that if he must build it fronting the east he had better glaze with matt glass. Other members, however, thought that would absorb too much light.

Herr JOOP suggested corrugated glass.

The CHAIRMAN thought that two sets of curtains—a white set to keep out the direct sunlight, and a darker set to regulate the light—might be used with good results. He (the Chairman) then showed a number of views, of whole-sheet size, of the mountains of Colorado and the Yellowstone district, by Mr. Jackson, of Denver, photographer to the American Government Geological Survey. He had taken a great number of 20 × 24-inch plates. He (the Chairman) then showed a number of new instantaneous photographs, by Muybridge—running horses, deer, cows, &c.

The only question in the question-box inquired how the addition of water at coating suitable for two emulsions, prepared with 6·7 per cent. of nitrate of silver and stored under alcohol one and three months respectively, could be determined. It was answered that no expressly-determined addition of water took place at this time, as there was only a question of expelling the superfluous alcohol by water, which could best be done by placing the emulsion in a muslin bag and suspending the bag for a few hours in running water; or, if a suitable washing-box were not to be had, water may be poured over it, and, after being well stirred amongst it, may be decanted off and the operation repeated six to eight times, and then let the bag be suspended to allow the water adhering from the muslin to drip. In this way the emulsion absorbs as much water as is required to give it the proper consistency.

This ended the business of the evening, and the meeting was shortly afterwards adjourned.

Correspondence.

THE LANTERN IN THE UNITED STATES.

To the EDITORS.

GENTLEMEN,—Replying to the inquiry of Mr. T. P. Hicks respecting America as a good field in which to work the optical lantern commercially, I am of opinion that there is a very great deal to be accomplished in that direction, and that large emoluments await any one who understands the business and enters into it energetically.

The prices of lanterns and their appliances are much higher in America than in England. As an example: plain uncoloured photographic lantern slides sell retail in England at one shilling and sixpence each. In a catalogue of American productions of similar class to which I have referred I find sixty cents. (half-a-crown) is given as the price. This does not apply alone to such pictures as those by York, Levy, and other European makers, which are subject to an import duty, but to those made in America.

Those who, like Mr. Hicks, know at what prices transparencies may be made or purchased wholesale, will readily conclude that the American price quoted leaves a very comfortable margin. Mr. York's slides—which, although not named as his in the American catalogue, but which I know to be his productions, or well-executed copies of them—also sell at the price mentioned, viz., sixty cents., uncoloured. Statuary slides, with the backgrounds stopped out, are charged a dollar and a-quarter, or five shillings and twopence-halfpenny each. This, too, is the price for comic slipping slides of good quality, lantern conundrums, microscopic enlargements, and subjects of a similar description.

Passing from pictures to appliances, the American prices are much in excess of those in England. For example: a four-inch mounted condenser, which in an American list is quoted at ten dollars (two pounds one and eightpence), has its counterpart in England quoted at twenty shillings. It is not easy just to know what is or what is not an American condenser. I remember, about a year ago, remarking to Mr. Muybridge that I thought, judging from the way his pictures of horses were projected on the screen, his condensers must be of a very inferior order; to which he replied that such could not possibly be the case, as they were made in the workshops and under the cognisance of Professor Henry Morton. The great optical ability of Professor Morton being well-known to me this was a "staggerer;" still, upon an examination of the condensers, I was impressed with their marked inferiority to what I had expected as emanating from such an acknowledged excellent source. This led to a strict investigation, when the reputed maker, the gentleman in charge of the optical department of the Stevens' Institute of Technology (of which Professor Morton is the President), upon taking them in his hands, pronounced them a very common French imitation of their lenses, although purchased from a reputed dealer in the genuine article. When I last saw Mr. Muybridge he had failed to obtain satisfaction from the unscrupulous vendor.

The knowledge of sharp practice of this kind introduces an element of difficulty in speaking of the comparative merits and prices of lanterns of the more pretentious class; but I think the relation between those of England and America, as regards prices, will prove to be somewhat similar to that shown to exist between those of slides, which are somewhat higher—in some cases double the price charged in London.

It is difficult to say *where* in America a lantern business could best be established; but for two reasons I would not advise New York as a suitable locality. First: the "New Yorkers" are an exceedingly busy race of people, and the lantern does not seem to have found a congenial home there yet, and hence it may prove uphill work to establish a business there. Secondly: there is a gentleman who, if I am rightly informed, was at one time associated with the Polytechnic Institute here, who has avowed his intention of trying the experiment of selling lanterns and lantern slides and appliances of English manufacture in New York at *English prices.* Philadelphia being a much more likely city in which to establish a good business with a reasonable prospect of success, I would suggest it as the place of all others in America in which to found a base of operations.

If Mr. Hicks, or any other active lantern manufacturer, will establish a business in Philadelphia on English lines he will confer a boon upon many photographers who would willingly invest in first-class lanterns in which to exhibit their pictorial productions were the high prices not prohibitory in a large degree.

Next to Philadelphia, Boston would offer the best field of operations; but it would be always inferior to the larger city as regards prices and demand.

Hoping this reply will prove satisfactory,—I am, yours, &c.,

Woodgreen, February 7, 1884. J. TRAILL TAYLOR.

CLEARING AND REDUCING NEGATIVES.

To the EDITORS.

GENTLEMEN,—Having read your leading article on *The Treatment of Negatives After Development*, and your concluding desire for a report of the results, I beg to say that for some time I have been using citric acid in the alum bath before fixing, and, as you say, the brilliant appearance is wonderful in comparison with using the alum without citric acid. This, to my mind, is the proper time to use the alum and citric acid, instead of after fixing, for clearing purposes, because the pyro. stain is not nearly removed until the negative has passed through the fixing bath. This you will readily notice by taking a developed and fixed negative by the usual method and having a decided pyro. stain upon it. If you put it into the alum and citric acid you will see an improvement, but not until it has been put into the *hypo.* does it completely vanish.

I have a pet mixture for reducing negatives which I have used for the last two years, and find it all that can be desired:—Take a one-ounce empty pyro. bottle, nearly fill it with Edwards's intensifier, and drop three biggish lumps of cyanide into it. When the cyanide has dissolved get another one-ounce pyro. bottle, half fill it with the above, and three parts fill the bottle with water. The negative to be reduced must first be put into the alum bath for a few minutes to prevent frilling, then washed and watched attentively while in the reducer, as a minute or two will be sufficient.

The reason more water is added to the mixture after the cyanide is dissolved is because it acts as an intensifier until some of the effect of the mercury and iodide is counteracted by dilution; so one can readily tell how much water to add, it being most wise to add a little at a time until it is found that it reduces as desired. When it has been got right it will reduce a number of negatives, and simply wants strengthening now and then from the strong solution.

Should any person, through carelessness, reduce it too much it can be very greatly strengthened by simply washing and leaving it in the hypo. bath for some time.—I am, yours, &c., ALFRED E. DIGHTON.

Sheffield, February 9, 1884.

RATIONAL DARK-ROOM ILLUMINATION.

To the EDITORS.

GENTLEMEN,—*Lucus a non lucendo* being the motto of all theorists on the above subject, permit me very humbly to emphasise one or two points very frequently lost sight of when "a safe light for the dark room" is considered.

The question is, at once, one of interception and transmission—of the maximum amount with the minimum activity of light. The total quantity of light must ever depend upon the *tint,* shade, or strength of the medium; and the quality—that is, the actinic or kinetic power—upon its *hue,* colour, or chemical peculiarities. Quantity and quality must ever be variable, both from external and internal causes—in the latter case the most important variations being dependent upon the different sensibilities shown by various salts to the same rays.

My principal object in thus troubling you is to suggest the great benefit to be derived, when dealing with this matter practically, from ever keeping in mind the *modus operandi* of Dame Nature in painting the flowers and in giving them their perfumes: the power, so to speak, of natural selection which organic and inorganic compounds exercise with regard to the solar rays, and the principles involved in absorption and rejection; and, lastly, though by no means least, the logical sequence of thought accruing to one who looks upon solar light not as composed of seven colours so much as of three. Notwithstanding my respect for the woundrous power of the number "7"—for the seven natural musical intervals, for the seven churches of Asia, for the seven champions of Christendom, and for the seven deadly sins—I do not think that my opinion that all questions relating to colour can thus be more clearly, comprehensively, and rationally grasped, should justify anyone in concluding that I have taken leave of my seven senses.

As the red, orange, yellow, green, blue, indigo, and violet hues in the solar spectrum have not hitherto been proved to be due to seven magical elements, and as the infra-red and ultra-violet rays seem in many respects to blend, so to speak, into a similar repeated series of invisible colours, let me briefly state—First: that all visible colours are either the primaries, red, yellow, and blue; the secondaries, orange, green, and purple; the tertiaries, citron, olive, and russet, or a mixture of these. Second: that red + yellow = orange, yellow + blue = green, red + blue = purple, orange + green = citron, green + purple = olive, and orange + purple = russet. Third: that, to any single colour, the complementary or most harmoniously-contrasting hue in any class is a mixture of the other two colours in that class, whether primary, secondary, or tertiary; and that, conversely, a mixture of any two colours in a given class will have as its complementary the remaining colour in that class. Fourth: that this holds true in an especial degree in all natural, visible colouring. Thus, the particular hue of green reflected to our eyes from (say) a cabbage of necessity depends upon the nature of the red absorbed. Furthermore: bromide of silver in gelatine is most affected (as the colour of a commercial dry plate would lead one to suppose) by diffracted solar light between the lines F and G, otherwise by the indigo-blue rays. Hence, here we deduce that the complementary colour will, above all others of equal brilliancy, tint, or strength, be the best wherewith to stop out or prevent the action of these rays; and, because indigo-blue tends to red, we find that the pure orange—which would be the complementary were the blue the pure primary blue, inclining neither to red nor yellow—must have a touch of green in it. *Cæteris paribus*, this may easily be tested as far as photography bears upon the action of sensitive salts. It should ever be remembered, also, that opacity of medium—that is, various thicknesses of "ruby," "orange," or "canary"—alters the *quantity* of light only, much in the same way that an aggregate mass of the straw-coloured and white (really pale blue) blood corpuscles appears crimson-red.

This extension and combination, rather than summary, of Sir David Brewster's and Sir John Herschel's theories will, hash though it be, derive confirmation from any experiments made upon the broad lines laid down by Kirchhoff, Angström, Lockyer, Abney, &c., the only difficulties being those inseparable from the imperfect state of our knowledge as regards the "scientific frontiers" of biology, kinetics, and chemistry when brought face to face with such empirical terms as "actinic rays."

In conclusion: I may confess to having purposely avoided all mention of such substances as sulphate of quinine as not directly touching the question, and as having a tendency to confuse. H. B.

Edinburgh, February 8, 1884.

Notes and Queries.

In reply to a query by I. K. T., in our issue of the 1st instant, the name of J. S. Brown, High-street, Bridgewater, may be added to those already mentioned as qualified to supply his requirements.

In reply to "Novice," a solution of shellac in methylated spirits of wine will form a better coating for his dish than paint. It should be made rather thin, and several coatings must be given, allowing the preceding one to become dry before another is applied.—George B. Fox.

Neither shellac nor paint, Mr. "Novice" (replying to a query in last Journal), is the correct thing for coating a wooden dish having a glass bottom; but an application of melted wax, and this made very hot indeed previous to application, will leave nothing to be desired.—S. S. R.

James Keeley writes:—"Will you kindly tell me if the chloride of lime is the ordinary or commercial chloride of lime given in formulæ."——In reply: The substance named and required is the popular "chloride of lime" of commerce, procurable everywhere. In strict nomenclature it, perhaps, ought to be designated "chlorinetted lime."

W. S. is desirous of knowing whether an old lens by a reputable maker who does not now advertise is a bargain or not at a certain price at which it has been offered to him.——We decline giving an answer to a query of this nature; but have no hesitation in saying that we have never known or heard of a bad lens by the maker named.

Can you or any of your readers inform me if there is a photographic society existing in Birmingham? I have looked in vain for an advertisement of it. If not, are there any insurmountable difficulties in the way of forming one? I see Manchester, Cheltenham, and other places have one, and why should not we?—One who Would Like to Join.——In reply: The matter rests in the hands of those more nearly concerned, namely, the photographers of Birmingham. Perhaps this hint may "wake them up."

Developing after M. Audra's manner I find very good when the solutions are new; but, when using it the other day, after leaving it for about three months, I found that when the iron was added to the oxalate a precipitate was formed, which appeared to me to be lime. The negative was only half developed, and nothing would move it from that state. I should feel much obliged if you would insert this among your *Notes and Queries*, as I should like to know if there be any remedy for it, and what is the cause of the same.—A. McKinnell, Jun.

In reply to "Broken Case:" I think the best thing a photographer can do is simply to ask liberty to display a photograph. Indeed common sense shows it is presumptious to do so without the permission of the individual, and when solicited to withdraw a card from his show-case it is certainly his duty to comply at once. His immediate non-compliance, however, does not justify the person in smashing the case, and such conduct *is taking the law into his own hands*, for which he is held amenable. Therefore get the broken frame repaired, and present the account for payment, and if he refuse to pay take out a county court summons for the same, and he will be obliged to pay with expenses.—Jno. Hicks.

Formula:—In the manufacture of bromo-argentic gelatine-emulsion plates with the addition of either ammonia or excess of bromide of ammonium or potass, or both combined, or excess of bromide in slightly acid condition (boiled or digested, and 120° Fahr.), to obtain the required speed. Also the plates coated in various ways.—Result: In the finished dry plate the bromide of silver is granular and has always stains and markings, which develope up with more intensity than other portions of the plate. If rubbed with the finger previous to using they present a polished, metallic appearance. If the emulsion be made with exact equivalents, &c., at 120° Fahr., cooled quickly, set, and washed, there is hardly any trace of the markings, and a *very fine* bromide. But the plates are too slow for portraiture. If you or any kind reader would inform me how rapidity may be gained with fine bromide of silver, and freedom from the above stains and markings, it would greatly oblige.—C. J. H.

Perhaps you will kindly give me the information I ask. I have a half-plate portrait lens, eight and a-half inches focus, and a half-plate square camera—an old-fashioned one—which I wish to use for enlarging purposes with a lantern similar to that of M. Hutinet's, which you have described in the Journal and Almanac. Are they suitable? And, if so, what size ought the lantern to be that is used with them? And how far should the negative be placed from the ground glass of the lantern? I shall esteem your answers a great favour.—John Robert Wilson.——In reply: The lens mentioned should answer the intended purpose quite well; so also will the camera, but only as a means of holding the plate and the lens rigidly fixed. Any size of lantern will answer that will prevent an escape of light. We should advise Mr. Wilson to discard the camera, and construct the various mechanical parts in accordance with the description of the Hutinet apparatus which we published. The negative must be placed at such a distance from the ground glass as to cause none of the granularity of the surface to be shown.

W. Reade inquires:—"1. What can be done with an over-dense negative? I have two or three which I have *over-intensified*, full of detail, and good otherwise.—2. Is there really the difference in lenses represented by the price; for instance, a certain lens by one maker seems obtainable for £2, whilst it would be £12 from another?—2. Could you give me the names of one or two of the best enlargers in London, regardless of everything—I mean *unfinished* enlargements? I am not particular what process, or what kind of paper. *Clearness* would be the *only* consideration with myself—no matter whether light or dark or what colour.—4. Are Hutinet's and Morgan's papers ready-sensitised? And in what way are they better than the ordinary paper, or, rather, I should say, are they better?"——In reply: 1. Apply a solution of ferric sulphate, by which the intensity will be reduced.—2. From the fact of such differences existing in price, corresponding difference in quality may reasonably be be inferred.—3. See the advertising pages of both our Almanac and Journal.—4. A few trials will establish the relative merits of special brands of sensitive paper. These our correspondent will have to make for himself.

Photograph Swindle.—At the Salford Police Court, on Tuesday last, the 12th inst., William Henry Bird, canvasser, was charged with obtaining money by false pretences. On the 12th January prisoner went to the shop of Emma Harrison, 17, Corporation-street, Salford, and represented that he was a photographic canvasser. He said he was from "Platt and Co.," 76, Market-street, Manchester, who were photographers in opposition to Banks, and were selling their "tickets" at a very low price. He added that that was the last day for selling the tickets. She gave him an order for two tickets, and handed him 2s. The tickets, however, did not arrive.—Another case was one where in a similar manner prisoner had obtained 3s. from Hannah Leigh Sayers, beerseller, 57, West Craven-street, Salford. Police-constable Sainsbury, of the city police, received the prisoner into custody in Manchester on the 2nd inst. from a son of the prosecutrix Harrison, who had been in search of the prisoner since they had found out the matter was a swindle. Prisoner, who had been convicted four times previously for fraud, was committed to the sessions for trial.

Charge of Fraud against a Nottingham Photographer.—On Wednesday, the 30th ult., at the Loughborough Police Court, George Daniells, of Nottingham, was charged on remand with obtaining two shillings by false pretences from Fanny Upton, at Loughborough, on the 10th of August.—Mr. Rowlatt appeared for the prosecution, and Mr. A. St. John Stevenson, of Nottingham, for the defence.—A few days previously defendant was brought up on two charges of a similar character, one of which was dismissed and the other withdrawn. The present charge was adjourned for the production of further evidence.—The evidence of the complainant, Mrs. Woolley, and Lucy Groocock, as given at the former hearing, was read over, the facts of which were that the defendant went to the residence of Mr. W. E. Woolley and asked to be allowed to take a photograph of the building for architectural purposes. Upon his representing that he had taken Garendon, Southfields, and other places in the neighbourhood, Mrs. Woolley allowed him to take the photograph, and he set up his apparatus as though he were doing so. He afterwards went to the servants and took a photograph of the complainant (Fanny Upton) and others. She ordered two copies of it, and paid defendant two shillings on the understanding that they should be sent on. About six weeks after the photographs should have arrived the complainant wrote for them, and received a post-card stating that they would be forwarded. She had not yet received them.—In defence, Mr. Stevenson submitted that upon the law there was no case against the defendant.—The Bench retired to consult, and on their return into court said they preferred to hear the evidence for the defence before deciding upon the point of law.—Mr. Stevenson pressed for a decision, contending that according to the law the false pretence must be a misstatement made at the time, and not a statement depending upon a future contingency, which he submitted was the nature of the alleged false pretence in this case. —After a consultation with their Clerk, the Bench said this was an important case, and they had made up their minds to hear the whole case before giving any decision.—Mr. Stevenson said until the Bench had decided whether there was a *primâ facie* case, and the defendant had been asked for his defence, he could not proceed; he was prevented by law from doing so. He had a duty to perform to his client, and he should discharge it fearlessly.—The Chairman ultimately announced that the Bench had made up their minds to commit for trial unless some evidence called for the defence caused them to alter their decision.—Mr. Stevenson still demurred, and the Clerk said that unless Mr. Stevenson went on with the case his client was now committed for trial.—Mr. Stevenson: Really I don't want to say anything discourteous, but I never heard anything like this before in my life in any court of justice. Mr. Rowlatt knows well this is irregular procedure. —The defendant was then cautioned, and in reply to the usual question said—"I decline to plead on the ground that the magistrates decline to decide upon a point of law raised by my solicitor."—Mr. Woolley: But they have given a decision.—Mr. Stevenson: Well, we say not; and that is the defendant's statement. I ask the magistrates do they still decline to rule?—The Chairman: We have committed him for trial.—Mr. Stevenson: Very well, we must get a mandamus.—Defendant was formally committed for trial at the next Quarter Sessions.—Mr. Stevenson asked that, considering the paltry nature of the charge, defendant might be admitted to bail on his own recognisance.—Mr. Rowlatt opposed the application, and the Bench decided to allow the same bail as before, namely, defendant in £50, and two sureties £25 each.—*Nottingham Evening Post.*

Exchange Column.

Wanted, *Aide Mémoire de Photographie pour* 1884, in exchange for THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1883 and 1881.—Address, E. EDWARDS, Silver-street, Bridgewater.

I will exchange a quantity of dry plates, any size, for a portrait or view lens by a good maker, or anything useful in photography.—Address, C. PARSONS, 36, Orbel-street, Battersea-park.

Wanted to exchange 250 gross of gem mats and preservers and fifty gross of gem trays for anything useful in photography or offers.—Address, F. WALTON, photographer, New Briggate, Leeds.

What offers for a splendid tea service of forty pieces, ground laid, raised enamel, and massively gilt, cost £4 10s.? Will take anything useful in photography.—Address, 30, Hope-street, Hanley, Staffs.

I will exchange a good 15 × 12 Kinnear camera and doublet lens, by Burr, London, two slides and case, for a good 10 × 8 size with lens complete.—Address, ARTIST, 18, Dennetts-road, Queen's-road, Peckham, London.

I will exchange the last twenty numbers of THE BRITISH JOURNAL OF PHOTOGRAPHY for ferro-prussiate paper or anything useful in photography.—Address, C. ESKELL, 2, Osborne-place, South Kensington, W.

I will exchange, mounted, water-colour paintings from nature by a first-class artist; number, sizes, and subjects on application. Wanted, Dallmeyer's 8 × 5 rapid rectilinear lens. Good camera and three double slides not objected to; also Dallmeyer's 1B lens, or offers.—Address, MAY, 2, Brunswick-terrace, Penrith.

What offers in exchange for a new cuckoo clock, made to stand on bracket in hall, a first prize from a draw, strikes hours and half-hours, value sixty shillings, photograph and size two stamps, also eleven volumes of THE BRITISH JOURNAL OF PHOTOGRAPHY from 1870 to 1880? Wanted, a dark tent or a good wide-angle lens for all kinds of outdoor work; must take pictures up to 10 × 8 or 12 × 10.—Address, W. BROOKE, 62, Town-lane, Shepton Mallet, Somerset.

I will exchange a cottage window, with folding sashes; a number of backgrounds, decorative and plain; a Cussons' posing chair, with movable arms; see-saw, nearly new, by Seavey; a Seavey plaque, frame, and background, nearly new; a patent turn-table for posing chair, by Marion, quite new; head-rests, by Harrison; Haddon Hall steps. Wanted: a powerful rolling-press, with plate about 24 × 18; must be in good condition.—Address, Mr. WINTER, Midland-road, Derby.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

A LONDONER.—Both the houses are highly respectable, and you may rely upon all the goods you purchase from them.

A. Z.—The gelatino-chloride process will suit your requirements best. Give with it a full exposure, and use a weak developer.

A. A. A. (Victoria-street).—The crystals of nitrate of silver being fifteen or twenty years' old, and slightly discoloured, will be no detriment to the salt. You may safely strengthen the bath with it, just the same as if it were quite new.

ALBUMEN.—You have been supplied with something which is certainly not kaolin, or it would not have precipitated the silver as you say it has. Better make up a fresh bath now, and procure some genuine kaolin for us when it requires decolourising.

S. S. S.—Mr. W. B. Woodbury will, no doubt, supply you with a suitable paper. If he cannot supply it himself, he will no doubt direct you to the right channel for obtaining it.

F. F.—We have read the letter, and returned it to you as desired. You will see our opinion of the affair in our answer to "C. C. B." last week. This we endorse, after reading his letter to you.

R. SMALLEY.—If the result forwarded be the best the lens can produce you will certainly be fully justified in returning it. We should imagine no objection will be made to exchanging it for another.

AMATEUR MECHANIC.—Yes; pine will do quite well for a camera; but, while you are about it, why not employ mahogany? It will not cost much more, and a less thickness will be required. It will also prove more durable.

H. SOLTER.—The negative arrived broken to fragments; but we can see that it is a decided case of green fog. Perhaps it arises from over-cooking, or, what is more likely, the gelatine you employed was unsuitable. Try another sample next time.

R. S. WARD.—We are not surprised that the druggist in your town cannot supply chrome alum. Few druggists keep the salt in stock, as they have little or no demand for it. Any operative chemist or photographic material dealer will supply your wants.

I. J. K.—You will find some designs for studios in the English translation of Liesegang's *Photography*, published, we think, by Sampson Low and Co. The light should not come nearer the floor than about ten feet six or so, according to the width of the studio.

P. J. BURT.—You had better get some carver and gilder in your neighbourhood to give you instruction in renovating old gold frames. We cannot undertake to do so in this column. We know nothing whatever of the "restorer" named, so cannot give you its composition.

AN ASPIRING OPERATOR.—If the examples forwarded are a fair specimen of your work we do not think you will be justified in expecting anything like the salary you mention. Operators capable of producing far more artistic work than yours are to be had for very much less.

F. T. DAWKINGS.—There is nothing at all extraordinary in a solution of gelatine remaining fluid and refusing to set. From some cause or other—probably from the solution being kept at a high temperature for too long a time—it has become decomposed. Better throw it aside now and prepare a fresh batch.

E. E. DAVIS.—Evidently the cyanide of potassim is of very inferior quality; otherwise such a large proportion would not be required to make a solution which will only fix collodion positives in from four to five minutes. If the salt were good, and used in the proportion named, we should expect it to fix the pictures in a few seconds.

H. BOISSONNAIS (Geneva).—The patent in this country for the Eastman coating machine has expired, therefore any person is at liberty to make one for himself. They are not articles of commerce. Possibly Mr. Eastman himself could supply you with one. His address is "Rochester, New York." We are not aware that any coating machines are made for sale in England.

A.B.—1, 2, 3. All will depend upon the amount of silver the emulsion contains in the first instance, and the thickness of the coating on the plates. When travelling on the continent we should quite expect the old fixing solution is not worth saving, with a view to the recovery of the silver it contains. If the silver be deposited on the trees in patches, we imagine the plates must be at fault.

RECEIVED.—John Harmer; W. T. Wilkinson. In our next.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 20th inst., the subject for discussion will be—*On the Best Methods of Obtaining Black and White Negatives on Dry Plates.*

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician,
For two Weeks ending Ferruary 13, 1884.
THESE OBSERVATIONS ARE TAKEN AT 8.30 A.M.

CONTENTS.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1242. Vol. XXXI.—FEBRUARY 22, 1884.

THE PRACTICABILITY OF TONING AND FIXING IN ONE OPERATION.

Just now the subject of the permanence—or, rather, the want of permanence—in silver prints is once again engaging the attention of the photographic fraternity. At several of the societies of late (both in London and the provinces) the matter, in one form or other, has been brought under consideration; indeed, it is seldom that anything in connection with silver printing is mooted now without its cropping up. But, as on former occasions, no new light has been thrown upon the subject.

It has been at many times asserted by photographers of the old school that if we were to revert to the ancient process of toning, with our modern knowledge, a far greater degree of permanence would probably be secured. This remark is so frequently reiterated that it may not be amiss to inquire if the thing be really practicable nowadays; and, if it be, whether a greater degree of permanence can reasonably be expected to accrue. Now, as many photographers of the present day have had no practical experience with toning or fixing in one solution, and some have really no idea how it is accomplished, we shall here give the process in detail, and then make a few practical remarks on its bearing as applied to modern circumstances.

Here is a formula for a toning and fixing bath that we know was employed for several years in one of the largest London establishments, and the prints issued therefrom have proved to be as permanent as any that were produced at that period:—First, three-quarters of a pound of hyposulphite of soda was dissolved in sixteen ounces of water. Then a fifteen-grain bottle of chloride of gold was emptied into two ounces of water, dissolved, and added *very* gradually and with vigorous stirring to the hyposulphite solution. Next, two drachms of nitrate of silver in two ounces of water were added in a similar manner. After standing for twelve hours or so, during which time the sulphur liberated by the acidity of the gold and silver subsided, the bath on filtration was ready for use.

When the prints were taken from the frame they were washed in water to remove the free silver, but not to the same extent as is now done, prior to toning by the alkaline method. They were then immersed in the toning bath. The first change in colour was to a foxy red, similar to that observed when an untoned print is placed in a plain solution of hyposulphite of soda. After a time the print gradually assumed a brown tone, then a purple, and finally a black, more or less cold according to the time it was allowed to remain in the solution. The time occupied in toning varied considerably, according to the temperature and activity of the bath. It was no uncommon thing for the prints to take several hours in acquiring the desired tint. Sometimes, when the bath was very inactive, the prints used to be left in all night on the chance of their being finished by the morning. When the prints were deemed to be sufficiently toned they were removed from the bath and washed more or less perfectly, the same as at present.

Frequently, when the bath was new, although it then contained its maximum of gold, great difficulty was experienced in getting anything beyond a purple-brown tone. When this was the case it was customary with many operators to immerse the prints direct from the frames without previous washing; then the darker tones were the more easily obtained. As the solution became older black tones could be obtained more readily. The bath, when once made, was rarely discarded; for, when its bulk diminished, new solution was made up and added to the old. The bath would continue to yield rich black tones long after it must have become quite exhausted of its gold, the colour obtained in this case being, doubtless, due to a sulphuretting action alone. Indeed, it is more than probable that, at all times, some part of the toning action was really due to sulphur, inasmuch as, until the bath had been considerably used and had thereby acquired sulphuretting properties, black tones could rarely be obtained.

At a late period of the toning-and-fixing-in-one-operation era, the most careful printers made it a practice to immerse their prints, after the desired tones were obtained, in a fresh solution of plain hyposulphite of soda, but the custom was by no means general. It should be mentioned, in connection with this system of toning, that the pictures must be printed *very* much deeper than for the alkaline process. This, in detail, was the old process of toning, and it did undoubtedly yield a very large number of prints which, to all intents and purposes, are permanent. It is for this reason many persons infer that if we went back to the old plan, and at the same time took care that the bath always contained sufficient gold to ensure that being the toning agent and not sulphur, and also that the prints were afterwards fixed in fresh hypo. and then carefully washed, a greater permanence would result.

Now, let us look at the facts and see the altered conditions under which the old process would now have to be worked, if it were again adopted, and inquire if such permanent results as were at times produced could now be expected.

In the first place, the albumen with which the paper was then prepared was salted to the extent of fifteen to twenty grains to the ounce, the albumen itself being diluted with water to the extent of one-third or more; hence the chloride penetrated deeply into the paper. Then this highly-salted and slightly-albumenised paper was floated for several minutes on (according to modern ideas) a *very* strong silver bath—from sixty to ninety, or more, grains to the ounce of water. Hence it will be seen that a large proportion of the chloride of silver forming the image was actually in the body of the paper—not merely on the surface. It may be here mentioned that, as the fashion for a more highly-glazed surface was adopted, black tones were obtained with greater difficulty than before, and a longer time was necessary in the toning bath.

At the present time, instead of the albumen being diluted with water and highly salted, it is used as concentrated as possible (a second coating being sometimes applied); and it contains only about a third of the quantity of chloride formerly employed. The coating is also dried very rapidly to prevent its sinking into the paper, so as to preserve the highest possible gloss. It is sensitised on a very much weaker silver bath than of old, and everything is done at the present time to keep the image as much as possible on the surface of the paper. Added to this, the negatives formerly used were very dense;

indeed, it was no uncommon thing for them to take a whole day to print, even in a moderately-good light. When printed the image was frequently seen distinctly on the back of the paper if it happened to be a thin sample. Now the negatives are made very thin, and print quickly; consequently the image rarely extends much beyond the mere coating of albumen.

These altered conditions under which the old process would now have to be worked should be borne in mind by those who advocate a recurrence to the plan of toning and fixing in one operation as a means of securing a greater degree of permanence.

HOME-MADE DEVELOPING DISHES.

From various communications recently received we are of opinion that the manufacture of specific examples of developing trays is a branch of home industry being practised by not a few, more especially by those whose facilities for purchasing these articles ready made are circumscribed either by remoteness from commercial centres or by other considerations.

There are several methods by which developing dishes may be formed without involving much expenditure of time, money, or even any special constructive skill. Of these, it is probable that a sheet of paper, the margins of which are bent up, will form the easiest. It is rather surprising how effective this paper-developing tray may be made. We have tested its efficacy on a 10 × 8 plate and find it to answer very well. The way—or, more correctly, *one* way—by which to form a tray of this class is to select a sheet of tolerably stiff, thick paper, and cut it one and a-half inch larger than the plate, turning up the edges so as to leave the bottom just a trifle larger than the plate for which it is intended. These turned-up sides are bent at the corner so as to lie against one of the sides to which the overlaps are secured by means of sealing-wax. A mixture of equal parts of bees'-wax and paraffine having been provided, and rendered quite fluid by melting, is applied all over the paper tray by means of a soft brush. When in use this dish is placed upon a slab of wood, millboard, zinc, glass, or any flat substance a little larger than the plate. One of the covering boards of an old dilapidated atlas was employed by us as the means for supporting the 10 × 8 dish to which allusion has been made, and it answered the purpose admirably. Those who have not made a trial cannot adequately realise how much wear and tear one of these paper trays will stand.

But by an extension of the paper system, on the evolution principle, a tray may be made which will prove very much more than a makeshift. By rendering paper plastic by immersion in a hot solution of gelatine, and shaping it upon a wooden mould of the required dimensions and form to the extent of four or five layers—more or less according to the thickness of the paper employed—a tray may be formed which, when dry and finished, will prove light, rigid, and unaffected by the developing solution. After it has been removed from the mould and become thoroughly dry it is first trimmed round the upper edge by means of a sharp knife or file—for it becomes so hard as to be better acted upon by a file than anything else—after which it receives a coating of common lac varnish. This, when quite dry, would prove sufficient protection for most purposes; but we have always preferred to give the tray a final coating of a solution of bitumen. As we have not found any sensible difference in the results obtained from the employment for this purpose of a solution of bitumen in benzole on the one hand, and the common Brunswick black of commerce on the other, we do not apprehend that special nicety in the selection is necessary.

For the tourist, home-made dishes of this description will prove very useful, inasmuch as they may be moulded to any form and made to nest inside each other; while in hot climates they will bear a very high temperature, having in this respect an advantage over either wax-coated wood or gutta-percha. The final touch in the manufacture of these *papier maché* trays is given by placing them in the kitchen oven until thoroughly hard.

A piece of thick, spongy millboard, of a kind sometimes employed in forming boxes and the covers of very cheaply-bound books, if steeped for some time in hot water, becomes softened to such an extent as to be readily moulded into the form of a tray. To this end the softening must be carried so far as to render it quite flaccid. In our last attempt at moulding a tray from this material the corners, owing to the brittleness and bad quality of the board, could not be got into form, so we slit them and overlapped the edges round the corners of the mould, applying strong flour paste to keep them in shape until the tray had become sufficiently hard to warrant its being knocked off the mould. This was then trimmed with a pair of sharp scissors and placed in a current of air until dry, after which it received as many coatings of asphaltum varnish as it could absorb, the services of the kitchen oven having been brought into requisition to aid in the drying of the varnish. From a critical examination of a French-made tray of great excellence which we had many years in use, we have arrived at the conclusion that it was made of like materials and in a manner similar to that which has just been described.

For travelling, and also for occasional home use, a tray devised by Mr. James A. Harrison, some years ago, will prove of great value. It consists of a light wooden frame, of dimensions to suit the size of plate used, hinged together at three of the junctions in such a manner as to open and pinch between the ends of the slabs a piece of waterproof of flexible material, such as thin india-rubber cloth, the fourth and open junction of the frame being afterwards fastened by a hasp or clasp of any suitable kind. When the corners of the rubber cloth are thus tucked up this makes a very convenient tray, the material of which may be changed to suit special requirements. For example: desirous of developing a paper photograph, we formed it into a tray by pinching the corners in the frame and then pouring in sufficient developing solution to serve the purpose. A few years ago we made an improvement upon this portable tray by rendering the laths expansible in the longitudinal direction, so that one frame served the purpose of forming dishes including a variety of sizes.

Gutta-percha, which was deservedly deposed from a position it once held as a recipient for the silver bath, answers well as a material out of which to form developing dishes. The facility with which a sheet can be moulded into a tray renders a description unnecessary.

Japanned tin is said to be much employed in the United States for developing dishes, but, from some observations made by a speaker at the Indianapolis Convention of the Photographers' Association of America, we imagine this class of tray does not meet with universal approval.

THE USE OF SULPHITE OF SODA.

While offering an excellent proof of the usefulness to photographers of our *Notes and Queries* column, an article by Mr. B. J. Edwards in our issue for the 8th instant raises a very important question in regard to the use of sulphite of soda in the developing solution, which valuable suggestion of Mr. H. B. Berkeley's has had so widespread an adoption that any tendency to prove that its use involves a grave defect must be examined with the utmost care.

The gravity of Mr. Edwards's charge is contained in the following words. Speaking of gradation of tone in dry plates, he says "your correspondent points out that this gradation depends to a great extent upon the plate. It is perhaps not generally known to what extent this is true of different makes of dry plates (which vary as much in their capabilities of giving true gradation as wet collodion at its best and at its worse); but, even with the most perfect plates, it is precisely in this respect that the sulphite developer has failed in my hands to give satisfactory results. It seems to cut off a little at either end of the scale. With normal exposure a little of the detail in the deepest shadows is lost, while, if the exposure be slightly increased, and the development pushed to obtain the required density, the delicate half-tones next the high lights are sacrificed."

Now, it is unquestionable that if Mr. Edwards's opinion be warranted by facts obtained from the experience of other workers, the use of this salt will be given up—at anyrate, by those who require the highest class of effect in portraiture. Mr. Edwards states that "already many of our best and ablest workers have discontinued its use, chiefly for the reasons stated above." We have from the earliest been such consistent supporters of the usefulness of the sulphite addition to the pyro. developer that we cannot receive Mr. Edwards's *dictum* without further proof, greatly as we esteem his knowledge and ability. In view of the importance of the question we earnestly express the hope that those of our readers who are in a position to do so will give their carefully-weighed opinion as to whether the use of sulphite does or does not restrict the range of gradation that any given plate is capable of showing. The answer will be of most value from those whose work lies with portraits more than in landscapes, for minute variations in gradation are unquestionably more readily observable in the former than in the latter.

We have ourselves a very strong opinion that Mr. Edwards's contention will not hold good; still, the point not hitherto having had special attention drawn to it, this opinion is subject to revision, and we propose making definite experiments to test the qualities of the sulphite of soda in this particular direction.

It will not suffice alone to show good pictures obtained by the employment of this salt. The record must be both comparative and continuous, and the question will evidently be one of considerable nicety, requiring both knowledge and discrimination on the part of an experimentalist before a judgment of value can be recorded.

It will be observed that Mr. S. Fry's experience offers a distinct negative to Mr. Edwards's; and, both manufacturers having had a long experience in professional portraiture, this conflict of opinion must naturally be most confusing to comparative outsiders.

Leaving now this phase of the subject with the again-expressed hope of contributions from our readers to aid in its complete elucidation, we may turn to the minor points raised in our correspondents' communications. Mr. Edwards considers that the advantage claimed for the sulphite is the absence of the usual non-actinic colour of the deposit; and, secondly, the facility of obtaining clear glass in the shadows.

We have to ask, with regard to the latter, where Mr. Edwards will find such a claim made? We have ourselves devoted more space than anyone to show the advantage of sulphite; but we have made no such claim, nor do we remember anyone having done so, and we do not think the facts would bear it out. As to the first point, though we may be accused of playing with words, we would say that the "non-actinic colour" is not in "the deposit," as Mr. Edwards writes it, but, instead, consists of a staining of the film. It would be quite possible to produce a similar colour in an oxalate developed negative subjected, after fixing, to the action of a bath of alkaline pyro.

Mr. Edwards's communication concludes by alluding to the preservative action of the sulphite upon pyro. solution, which, he states, is equalled by the use of glycerine and alcohol, or a trace of acid in the aqueous solution. It is true that Mr. Berkeley pointed out its preservative action in the pyro. solution, but that is the least part of the matter. Spirit and glycerine appreciably increase the cost of the pyro. If keeping the solution free from discolouration alone were in question nothing could surpass the effects of adding acid, as first suggested by Mr. A. Cowan, though, as was pointed out in our columns, a far smaller quantity than he recommended would answer the purpose. The function of the sulphite, we take it, is primarily, as often explained by us, to keep the negative from taking on the unpleasant yellow colour characteristic of pyro.-developed plates; and secondarily—and almost consequently—to keep the solution from becoming so muddy and dark-coloured during use as to make it actually inconvenient to work with.

Mr. Fry points out, in his communication last week, several incidental advantages which decidedly add to the value of the above-described qualities, such as saving of valuable time through non-stained negatives printing more quickly, and assisting the retouching, the image more closely approaching the lead-pencil colour.

Finally: we would say that to our knowledge there are still many expert photographers who have not adopted the use of sulphite, and it would be unfortunate for any intending experimentalists to be deterred from essaying a discovery of its merits. It is surprising that, after the continued praise the salt has received, it should not have been tried by almost everyone; yet such is not the case, and it occurs to us that a possible explanation in some cases may be found in the photographer having been supplied by the local purveyor with some other salt in lieu of the sulphite, which is by no means a common preparation on the shelves of even first-class chemists, to whom the photographer always turns when he requires some rare or little-used preparation. In substantiation of this view we may mention an instance that was recently brought to our notice. A photographer had informed a pupil of the advantage of the use of the salt, and the latter forthwith went to the nearest chemist to obtain a supply. On the next "lesson day" the pupil informed his master of his ill-luck in developing. Upon further inquiry it was discovered that the chemist had told him he had made an error. "It could not be sulphite but hyposulphite that was required," and he weighed a quarter of a pound out, which the pupil religiously dissolved and mixed into a one-ounce bottle of pyro.!

We do not suppose that our readers are likely to be so treated; still, to those who yet intend to try the use of sulphite the incident may possess some value.

Dr. Liesegang is publishing the eighth German edition of his *Handbuch der Photographie*, which is to appear in five volumes, treating—1st, the photographic apparatus; 2nd, the collodion processes, wet and dry; 3rd, the gelatine emulsion process; 4th, silver printing and enlarging; and, 5th, the carbon process—in all about 900 pages, with several hundred woodcuts.

We have received from Dr. Liesegang samples of gelatinised paper which, if introduced into this country, would, we think, prove useful in several ways. The paper, which is prepared for use with collodio-chloride, is of two kinds, one of which has a soluble, the other an insoluble, coating of gelatine, both presenting the surface and high glaze of a glass plate. In addition to its legitimate application in connection with the transfer of collodio-chloride prints to glass or porcelain, we see no reason why the soluble form should not recommend itself as a substitute for glass for negative purposes when travelling, the picture being subsequently transferred to glass as its final support. The surface presents all the advantages of glass for the application of either a collodion or a gelatine emulsion, and after development the transfer of the image would be easy. We hope to report upon this application shortly.

There seem to be now two separate "rings" in America, the purpose of which is to keep up the prices of dry plates and "freeze-out" competition. From a circular issued by one of these, we find that "in the opinion of this committee 'concert of action between manufacturers of dry plates and photographic merchants is essential to the maintenance of the established schedule of prices, and to the development and preservation of that friendly feeling the existence of which is so desirable among the *members of our trade*.'" The italics are ours. Meanwhile the hint thus broadly given may be taken by consumers of dry plates as distinguished from the "members of our trade" that it behoves them to look after *their* interests themselves. No wonder there is just now such an exodus of skilled and experienced dry-plate makers from this country; and, further, it will be little wonder if—seeing that even with the lower prices prevailing in this country many consumers find it to their interest to be their own manufacturers—the effect of the "ring" will be to decrease rather than increase their trade.

According to a provincial contemporary, "the printing world is much disturbed by the discovery of a new process which enables any number of copies to be taken of the oldest book without setting a line of type. A compound has been discovered which may be spread upon a page without in the slightest way injuring the paper, and which refuses to rest upon ink. It can easily be removed to a stone, and there becomes the matrix for stereotype (?), or can be used for printing from at once. You hand your best beloved Aldine to the inventor of this new process, and he will return it to you without a stain or a mark, uninjured and only cleaned, and he will give you along with it an exact *facsimile*; letter for letter and broken stop for broken stop, of the volume which he has had in his possession for only a few days. Mr. Quaritch, the second-hand bookseller, is said to be thirsting for the blood of this too-clever inventor; but practical printers are already moving to see whether they cannot save the cost of resetting old editions, and, if certain practical difficulties are got over, we shall see a change not only in the productions of *facsimiles* of old books, but in the reproduction of modern books. It will no longer be necessary to keep type standing. A proof will be as good as a stereotyped plate. No book will ever really be 'out of print' so long as a copy of it remains. It will be nearly as cheap to reproduce a volume as to print an extra copy of a volume passing through the printing machine. Certainly we are progressing. Already water-colour drawings can be so well lithographed as to deceive the very artists. The time is not far distant when we shall photograph colours. And now that a book may be reprinted from itself, we may reasonably hope to find a method whereby oil colours may be multiplied from their own canvasses." Alas! for poor photography, that one of its most valued services should be thus rendered useless! No more old editions to be photographed as *facsimile*—no old engraving to be reproduced by photography, so that its owner cannot detect copy from original. We have only to wait "till certain practical difficulties are got over," and this, we daresay, will occur about the same time that colours are produced by photography, as indicated in the article we quote. The only comfort to be obtained is from the positive manner in which this latter assertion is made.

WHEN one door shuts another opens, however, and we therefore bring before our readers an account of the latest field that has been opened for photographic operations. A correspondent in a trade journal devoted to the interest of the chemists' business says:—"I see in your August number of the *Chemist and Druggist* you treat on photography. I enclose a few labels which I have always used for small phials. I print them from overplus sensitised paper at the time of printing orders for photographs. I simply write out what is wanted about ten or twenty times larger than what is required and photograph it, covering the remainder of the plate with yellow paper, shifting the sensitised paper as required or when sufficiently printed; I print in sheets of six or eight. I have now somewhere about 100 different plates. The pill-box top with the portrait is done by double printing.—Yours truly, F. T. MOORE, Waipawa, H.B., N. Z."—The editor of the paper replies:—"The specimens sent by Mr. Moore are very neat and attractive. The pill-box top bears his own portrait, and the other labels show considerable skill in penmanship. A 'superfine malt vinegar' label bears a photograph of what looks like a spirit still."

Is there not more than meets the eye in Mr. Moore's proposition? What splendid opportunities for the unsuspected introduction of contraband portraits! When Angelina lay sick on her couch through grief at the banishment of Mr. Lively Cashless, the very mention of whose name had been forbidden by stern parents, who would think of looking on the lid of a pill-box to find a "counterfeit presentment" of the hopeful lover, introduced through confederation with the chemist's boy? How fortunate photography did not exist a few hundred years ago, or one of Shakespeare's grandest works might never have been written! Romeo might have sought the apothecary on other thoughts intent than the purchase of injurious distillations. He might have sent by means of the surreptitious pill-box or the guileless phial enough of portraits of himself in the various costumes of the period to satisfy Juliet's longings till happier times arose. But portrait labels existed not in the days when *Romeo and Juliet* was written.

ACCORDING to *Cosmos les Mondes*, a waterproof paper and pasteboard can be produced by treating the surface of ordinary paper with an ammoniacal solution of copper, so as to partially dissolve the surface, and then allowing it to dry. Paper thus prepared is said to be equal to parchment. Our readers who have taken an interest in the discussion at the meeting of the South London Photographic Society upon Willesden paper will not fail to see the resemblance of the two methods. We cannot avoid thinking that if all the promises as to the qualities of the Willesden paper are carried out in its performance the material should be capable of a wide sphere of usefulness in photographic operations.

EVERY one is familiar with the widespread employment of paper in Japan, and a new era seems springing up in Europe. We have heard of its adaptation to the construction of water-pipes, drain-pipes, railway carriage wheels, and many other remarkable articles; so that cameras and slides, or camera stands, made from it would cause us no surprise.

THE other day *The Times* gave an account, which came from Consul Jade, of Christiana, of still another new paper-making material—white moss, found in Norway and Sweden, which grows, dies, and accumulates in vast beds, gradually becoming so disintegrated as to be prepared by Nature herself for immediate use. It is stated that paper and pasteboard—even to a thickness of three-quarters of an inch—made of the material have been shown. Either of them is as hard as wood and can be easily painted and polished, and has all the good qualities, but none of the defects, of wood, as it neither cracks nor warps. Between this new material and the Willesden paper it will be surprising if some exceedingly useful photographic product be not the outcome.

THERE is even asbestos millboard advertised for use in the laboratory as the best material for placing over Bunsen's burners, "being cheaper, more durable, and less liable to crack the vessels than wire gauze." It ought to be useful for such purposes, and, as the cost is not twopence for a piece four inches square, the price should form no impediment to its acquisition.

THERE is no subject in photography which young photographers, or those who have not made a special study of it, are apt to misconceive in a greater degree than halation. Notwithstanding the innumerable definitions of the term and illustrations of the subject that have appeared in this Journal at intervals during the past twenty years, there are still some who imagine halation to be a reflection from the back of the dark slide, and some who, like Mr. Geddes, of Arbroath, feel aggrieved at space not having been found either in the ALMANAC or JOURNAL for the enunciation of their sentiments respecting this phenomenon, forgetting that we may have taken this step from the very kindliest of motives. Halation proper cannot be remedied, as alleged, by the mere placing of a piece of blackened cardboard behind the plate. The particular evil, whatever it might have been, that was said to be remedied by this treatment, was certainly not halation, for which (as we and numerous other writers have pointed out) *optical* contact in contradistinction to mere mechanical contact between the light-absorbing backing and the glass is a *sine quâ non.* We do not like to discourage ardent investigators, but much less do we like to see anyone placed in a false position when we can prevent it. We may embrace an early opportunity of saying something on a few of the phases of internal reflection of light which inpinges upon the surface atoms of the silver haloids.

PHOTOGRAPHIC LENSES FOR BEGINNERS.

AMONGST the questions which I have been asked by those who intend to take up the practice of photography there is none so common as "what lens would you recommend me to purchase to begin work with," or, "what lenses." It is a question not very easy to answer, and the answer to be given is now a very different one from what it would have been a few years ago.

In the days of collodion there could be little doubt as to the best lens for an amateur who, as in the case of most amateurs, aspired to do everything—portraiture, landscape work, and architecture included. We should then have had little hesitation in recommending an instrument of the group or universal type. It was possible with such to do portraits either in a studio or out of doors, and in fact at times, with all circumstances favourable, even in an ordinary room, the exposure being, of course, somewhat protracted. It was an excellent instrument for instantaneous work; and as such work usually requires the inclusion of but a narrow angle, the lens could be used for a plate small in relation to its focal length, and with full, or nearly full, aperture. With a wet plate and a universal lens and full aperture, the same actinic impression will be approximately produced as with a symmetrical lens on a rapid gelatine plate with a similar exposure. The apertures bear the relative area of about twelve or fourteen to one. The universal or group lens does not distort; it is, therefore, useful for architectural purposes, and when used with a small stop makes an excellent landscape lens.

It is to be observed that in using this lens for general landscape work it is usually necessary to make several extra stops smaller than those provided by the makers. I do not know why it should be the case, but certainly it is usual with a group lens to send out no stop with aperture smaller than about $\frac{f}{15}$ or $\frac{f}{20}$. It should be borne in mind that if this lens is to be used for landscape work it is necessary to have a set of stops bearing exactly the same relation to the focal length that the stops of a landscape lens of the same focus would be provided with; that is to say, we should have stops as small, at anyrate, as $\frac{f}{40}$. Possibly there is some idea in the minds of the makers of the lenses that there would be something ludicrous in the issuing of a lens of the portrait type about three inches diameter with stops as small as, perhaps, a quarter or three-eighths of an inch diameter. This is necessary, however, and I believe the want of success sometimes met with by those who attempt landscape work with such instruments arises from the fact that they do not understand the necessity there is to use stops as small as would be used with the ordinary landscape lenses of the same focal length for the purpose of gaining depth of focus.

I am, however, not now considering the lenses best for collodion work, and in remarking thus on the group lens I am wandering from my subject. The question on which I would say a few words is—first, what is the best lens for an amateur to purchase who can afford but one? The answer which will come to the lips of most without hesitation will be—"a lens of the rapid landscape type;" and certainly there is much to be said for this instrument.

With such a lens it is possible, under favourable circumstances, to take portraits even in an ordinary room, and this especially if the diaphragm cell which has been fixed by the maker be enlarged so as to give the full diameter of the lens, or very nearly so. In such a case we may work with an aperture of $\frac{f}{8}$ or $\frac{f}{6}$, and will get certainly as good definition as is required for portraiture; that is to say, if the instrument be by a good maker. The exposures in bright light will probably vary between ten and twenty seconds. Out-of-door portraits can, of course, be taken with such lenses easily, and with a very brief exposure.

For instantaneous work these lenses are excellent, although it is to be observed that in the case of such work the attempt should not be made to cover a plate whose length is more than a small proportion of the focal length of the lens. I consider that for instantaneous work it is seldom desirable, with a rapid landscape lens, to attempt to cover a plate whose length is much more than about half the focal length of the lens. Thus, for a half-plate we should use a lens of at least twelve inches focus; or, rather, as having but one lens we must take that as the starting-point, if we have a lens of twelve inches focal length we should not endeavour to cover, in instantaneous work, a plate larger than $6\frac{1}{2} \times 4\frac{3}{4}$.

It is needless to say that the rapid landscape lenses do well for architectural work when required to include no very large angle, and also for ordinary landscape work. In fact, the rapid symmetrical, or rapid rectilinear or euryscope, lens will, perhaps, bear the palm when only one lens is to be used. The last of those mentioned has one very great advantage for an amateur who attempts portraiture: it has a very considerably larger open aperture than either of the others. In fact it will work up to somewhere about $\frac{f}{7}$, at which it is just about twice as rapid as the other lenses mentioned, when these are used with the fixed stop as issued by the maker. It is quite true that at this aperture its defining capabilities, as examined under a high-power eyepiece, fall very far short of those of the English lenses referred to, and that, even stopped down to the diameter of their maximum aperture, it still gives somewhat less perfect definition. Nevertheless, the definition given with full aperture is quite as good as is requisite for portraits; at anyrate for such as are not to be enlarged. Altogether, where large plates are to be worked, the rapid landscape lens is, I think, the best for an amateur to purchase; but I would point out that for small-sized plates it certainly has a powerful rival in the cheapest and most ordinary of all lenses—the single landscape lens.

The single lens has more good points than it generally receives credit for, and this especially where it is not necessary to cover large plates or to include a very wide angle. There is a general tendency in the present day to perceive that we have been making too much use of the properties given in wide-angle lenses, and to restrict ourselves to the use of those of comparative long focal length with relation to the size of plates used. This gives the single lens a better chance than it has had for many a year, and there can be little doubt that it is coming to the front again.

The aperture at which a single lens of moderate focal length can be worked when only a narrow angle is to be included is considerable. In setting the limit of size at $\frac{f}{12}$ I am certainly not overstepping the mark. The definition given by some single lenses through an angle of about 30° with such an aperture is excellent. This aperture is, there is little need to remark, quite sufficiently great to enable instantaneous work to be performed with rapid plates.

Then there is to be considered, in the case of the single lens, the advantage of having but two reflecting surfaces instead of four. This advantage is greater than is commonly supposed, and is more felt in the case of dry plates than in the case of wet. The effect of reflection from several surfaces (besides the occasional production of ghost images or flare spots) is to introduce a certain amount of diffused light into the camera, with the effect of bringing about an effect closely allied to that of slight pre-exposure. Pre-exposure, as is well known, and, as was first pointed out by my friend Mr. J. Traill Taylor, is, in many cases, of advantage with wet plates, but with dry plates it is very seldom so.

Those who compare the image produced by a single lens and by a double combination lens, equal exposures and apertures being used, will perceive, especially with certain subjects, a decidedly greater amount of brilliancy in the image produced by the single than by the double combination lens. This quality of the single lens has sometimes been designated "penetration." Of course there is the drawback, in the case of the single lens, that a certain amount of distortion is produced. This distortion is, however, much less in extent than is generally supposed, and diminishes very greatly as the angle does; for all practical purposes it disappears entirely when we come to those angles which, as a matter of fact, give the most artistic results, namely, those of about 25° to 30°.

Nor is it to be imagined that to find all those good qualities it is necessary to obtain one of the very most modern makes of instruments. Some little time ago I tried one of the old-fashioned A. Ross's single lenses of twelve inches focus against one (of precisely the same focal length) of the most modern construction, which is sold under the name of "wide-angle." I found that the former would work at a somewhat larger aperture than the latter, and that when the stop was approached to the lens, and a small aperture was used, it would cover the same-sized plate with quite as good marginal definition.

If it come to a question of the *two* best lenses I should have no hesitation in recommending—first, a single lens of focal length somewhat longer than the plate; and, second, a rapid landscape lens of focal length as nearly as may be *double* the length of the plate. It is true that with neither of these can a very wide angle be included; but if the amateur be restricted in the number of lenses which he can purchase he must simply avoid attempting such subjects as include a wide angle, remembering that, at the best, they generally give poor results. W. K. Burton.

DARK-ROOM ILLUMINATION.—ACTINISM *VERSUS* WAVE-LENGTHS.

Dark-Room Illumination.

I now reply to Mr. G. D. Macdougald's comments on my statement that I was struck with the rapid falling off of the actinic power the further the plate was placed from the lamp, compared with the loss of luminous power, because I found that by exposing a rapid plate fifteen inches from the lamp I got a deposit in one minute, whereas with a plate coated with the same emulsion and developed with the same developer I could not get any impression in fifteen minutes, when exposed at a distance of twenty-seven inches. Mr. Macdougald says this is "impossible," because light diminishes inversely as the square of the distance from the source. The eye judges the amount of the luminous power of the light in a room by the general appearance of the various articles in it, and not by the photometric value of the light from any one point or colour.

I stated at a meeting of the London and Provincial Association that I thought to obtain an equal deposit on a film from a reflected as from a transmitted light—that we could have in the former case nearly fifty times more light in the room to work by than in the latter, supposing that the same burner was used in each case; but Mr. A. Cowan has proved that there must be far more luminous light than that. He found that by transmitted light he could obtain a deposit in five seconds; but with a reflected light, with more apparent light to the eye, he could not obtain a deposit in 180 times that period of time. Such being the fact, surely it was not surprising that I was struck with the rapid falling off of actinic compared with the apparent loss of luminous light.

Is there no explanation for this without the well-established law of inverse squares having to terminate its day of usefulness? To obtain a practically-safe transmitted light for the development of a rapid plate we have so to diminish the amount of light that, on looking at the lamp, we find towards the edges of the lamp there is a great falling off in the amount of light. This shows that the angles of incidence are sufficiently wide to refract the light back into the lamp instead of transmitting it; so that, if a plate be stood at a few inches in front of the lamp, nearly the whole of the light, both actinic and luminous, coming out of it will be received on the plate, and all around will be in darkness. But, when using the same burner in a reflecting-lamp, the light, instead of passing concentrated from its source to the plate, is first distributed all over the interior of the box, and the only light falling on the plate is that reflected from one small spot in the interior of the box, the remainder of the light, both actinic and luminous, being reflected in all directions into the room. Of course it does not matter how much actinic force there may be in the light reflected into the room, so that it does not fall on the plate; and as with the reflecting lamp light is equally distributed in all directions, the amount of actinic force reflected from any point in the box cannot exceed $\frac{1}{180}$th part of what it is when transmitted from the same-sized point of the flame.

There is another point we must not overlook, and that is that the film on a gelatine plate is white, and it is wonderful what a small amount of luminous light is required to see the details during development. The strain to the eyes, I am convinced, is due rather to trying to see points on the dark slide when putting in the plates, and in groping about for bottles, &c. With the weakest artificial light I have ever worked with I have never had any trouble in seeing the plate or in discovering which was the film side; but for everything else I had to trust wholly to touch.

I think where the greatest injury to the eyes is caused is in trying to see the marks on the graduated glasses. It would be a great improvement if we made our solutions to a certain equal standard, and used spoons or small ladles, by keeping the solutions in well-covered jars—one for pyro, one for ammonia, and another for bromide—with a glass or earthenware spoon in each. Each spoon should measure a drachm, or less. All one would have to do, when developing, would be to pour a certain quantity of water into the developing-glass, and for normal development take a spoonful from each of the three jars and pour in. An extra spoonful, or less, of either could instantly be added during development without any of the excitement or anxiety as to the fate of the plate that there is when trying to see the marks on the graduated measure, and without the difficulty there is to pour in only sufficient to come up to the mark, because in the dim light of the dark room one cannot see the amount of liquid coming down the neck of the bottle. By using spoons or ladles there would be no strain to the eyes, the developer could be prepared in one-quarter of the time, and we should get the exact quantity of solution we require without any difficulty.

Referring to Mr. Macdougald's other questions: if he will let me know his address I will send him a chart prepared by the Autotype Company, together with a paper read by Mr. J. R. Sawyer, at a meeting of the Photographic Society of Great Britain, and he will there find a thorough corroboration of my statements.

Actinism *versus* Wave-Lengths.

I will endeavour to explain more fully the meaning of the terms which I used in my articles on the subject.

In replying to Mr. W. H. Kirkby I used the same term that he did, namely, "actinism," as being synonymous with the term I had previously employed, viz., "actinic force." By these terms I mean that power in light which acts on the particles of silver bromide or other salt contained in the film. In speaking of the density of any transparent substance compared with that of the prism I did not, of course, mean that the two were actually of the same thickness or material; but that the resistance of any substance which transmits and changes the nature of the white light passing through it into a certain coloured ray must have exactly the same power of resisting as the prism at the angle of refraction which produces the same ray of colour, because the wave-lengths of both are equal. We know every coloured ray of the spectrum has a different wave-length after passing through the prism or other substance, and that the wave-length of each colour has a certain control over actinic force. This is shown by the different effects on a sensitive film. It occurred to me from the first that it was a somewhat singular fact that the sensitiveness of the gelatine film to the various colours was in an inverse ratio to their wave-lengths and the varying wave-lengths of the different colours. I thought I saw a counter or opposing force to that power (whatever may be its new baptismal name) which influences or acts upon the particles of silver haloid in the film. What I wished to show in my article was that there must be two distinct forces in light, and which is the stronger of the two depends on the colour of the substance which reflects or transmit it.

I will mention a few experiments to prove more clearly what I mean. In place of the coloured glass of the dark-room lamp let us first place a piece of ordinary transparent white glass, afterwards a piece of violet, then a piece of ruby glass, and expose a sensitive plate to each. On development we shall find that the first had allowed actinic force—that is, the power which had acted on the particles—to pass unchecked. We also know that all the rays constituting white light have passed through it. In the second case: we find that actinic force has passed through violet glass; but we know that the violet rays passing to the plate with this force have the shortest wave-lengths of any. And now comes the question —What has become of the other and longer wave-lengths? Old theory says they are absorbed in the glass; if so, is not this the only case known to science in which a substance absorbs anything without showing some result, such as expansion, chemical change, &c.? Is it not far more probable that the other rays of the spectrum, instead of being absorbed by the violet glass, are equalised by it and brought to the same wave-lengths as the violet, and the effect of white light passing through violet glass is the same as if the whole of the white light had passed through the prism at the same angle of refraction that the violet rays do? In the third case: with the red glass we find that the long wave-lengths have prevented the actinic force getting to the plate, or, at anyrate, in a very weak and slow manner. It might be objected that this was caused by a different substance being used in the manufacture of the red glass to that in the violet. But let us expose a plate to light passing through a prism which is one substance throughout, and here we find the effect on the plate the same at the two ends of the spectrum as with the two coloured glasses; or, in other words, that some counter-force in the light has been set free by the part of the prism where the red rays passed through which has prevented actinic force getting to that part of the plate, and at the violet end this counter-force has but little power. Herbert S. Starnes.

A METHOD OF INTENSIFICATION FOR GELATINE NEGATIVES.

There are, probably, not many photographers of the present day who would not admit the superiority of gelatine dry plates over wet plates for ordinary work. In spite of the difficulties and drawbacks attached to the introduction of a new process, involving the adoption of a new groove for working in, and the consequent additions to, and alterations of, plant and dark room and other arrangements, gelatine plates have now obtained a firm foothold in most studios, even to the extent, in some cases, of causing the total abolition of the silver bath for any purpose. There are times, however, which will occur to most of us, when we are apt to compare the old process with the new, and to think that the change is not an unalloyed blessing.

A distinctive difference between the development of wet and dry plates is that, with the former, it was not generally expected that full density would be obtained by the application of the developer alone, but intensification was so simple and easy, and so thoroughly under control, that it was hardly looked upon as a trouble. With dry plates it is far different; it is desirable always to obtain the requisite density with the developer. This, however, it is not always possible to do, owing not only to defects in the plate itself and errors in exposure, but also to errors of judgment caused by the deceptive appearance of the plate in the dim light of the dark room. Even when exposure and development have been fairly well judged it will frequently happen that upon examination the plate is found to need just a slight increase of density—just a little piling up of the high lights—to make it produce a brilliant picture. With a wet plate this would be accomplished almost before there was time to bestow a second thought on the matter; but intensification with a gelatine plate, and especially a very slight intensification, is not a task to be entered upon so lightly.

The methods generally employed are, as a rule, modifications of those used for wet plates; but owing to the deposit, in the one case, being upon the film and thus easily got at, and, in the other, being embedded in a mass of gelatine—itself a troublesome substance to deal with, requiring long washing to free it from soluble salts held within its pores and terribly liable to stain—a successful result is by no means equally easy of attainment. The acid pyro. and silver and acid iron and silver methods appear to be successful in some hands only; and those methods in which the deposit is first bleached by the action of a mercury salt and then blackened by the subsequent application of some other solution are open to this objection, if to no other—that it is very difficult indeed to judge how far to carry the bleaching action so as to secure exactly the amount of intensity required.

The method of working which I am about to describe I have found from experience to successfully cope with the difficulties ordinarily met with in portrait work, and, doubtless, would be applicable to work of any kind. The directions may, perhaps, make it appear that it is complicated; but in practice it will be found that the operations follow one on the other in very easy sequence—perhaps even, taking one negative with another, there is a little gain in point of time.

The negative, having been developed with alkaline pyro. and fixed, is taken out of the hypo. bath. Before washing, a judgment is formed as to whether it is too dense, dense enough, or too thin. In the first case it is washed and reduced by any approved method. In the other cases it is immersed in a bath of—

Protosulphate of iron	3 ounces.
Chrome alum	½ ounce.
Water	20 ounces.

Here it may remain a considerable time without injury; but the action will be complete in a very few minutes, and will be found to be similar to that of the acid and alum bath generally used for decolorising and clearing the film, with this important difference—that the deposit will have gained, instead of lost, density. It may happen that it is now too dense; but this is a difficulty very easily overcome by flowing over or immersing it in a weak acid solution. I use hydrochloric acid—about six drops to the ounce of water. At this strength it will be well under control, and yet be a sufficiently-active reducer.

If the negative should not have gained sufficient density in the iron bath it will, after a thorough washing, be in a more favourable condition for being acted upon by any method of intensification that I have yet experimented with than if the iron treatment had been omitted; but I have nearly always found it quite sufficient to treat it with a simple solution of bichloride of mercury in water. It is advisable to use this very weak to start with, especially if only a slight increase of density be desired. The resulting negative will have exactly the colour and appearance of a wet-plate negative intensified with pyro. and silver. If it require still more density it may be blackened with a solution of cyanide of silver, as in Dr. Monckhoven's method; but this will rarely be required.

The iron solution, if used over and over again, will, of course, in time contain a considerable quantity of fixing solution; but I do not find this affects its action in any way. The iron solution should not be allowed to come in contact with the film until the developer has been washed out of it, or an inky stain will result. The fixing bath, however, seems to secure this, either by simple washing or by some chemical action.

With regard to the permanency of the negatives thus treated with mercury I am not able to say much. It is only rarely that I have to proceed so far, and the oldest negatives I have so treated were made about a year ago. These appear up to the present time quite unchanged.

I make no claim to having introduced any novelties. The addition of protosulphate of iron to the fixing bath for the purpose of blackening and intensifying the deposit was recommended by Mr. R. Kennett in 1879. Shortly afterwards I found that the same effect could be produced if the negative were treated with a solution of this salt before the hypo. was washed from the film. The discovery of the strong intensifying action of bichloride of mercury on a film so treated followed as a natural sequence.

Alexander Mackie.

"ACTINISM AND WAVE-LENGTHS."

Mr. H. S. Starnes has far misjudged me when he thinks I credit him with arrogance and self-conceit; on the contrary, I ascribe to him qualities of a very different nature. Fertility, ingenuity, and resource are qualities which Mr. Starnes undoubtedly possesses. All the more dangerous is he when he gets on the wrong track, as he is at present.

I endorse all that Mr. Starnes has to say on theories—their birth and development. Will Mr. Starnes believe that I am not a crusty theorist, sticking to text-book law "up hill and down dale?" I am willing to accept his theory, or anybody's theory, that will explain a greater number of facts, or even an equal number, in a more intelligible way. But this is exactly what Mr. Starnes' theory does not do, as I shall endeavour to show.

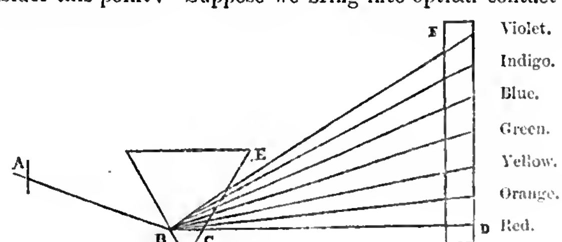
In the first place, Mr. Starnes is apparently not quite conversant with what is the generally-accepted theory. He has evidently got Brewster's ideas, or a theory very similar, and says that this holding has never been questioned from the time of its propagation. Now this is not the case. The theory that asserts that the prism is capable of splitting up white light into actinic, luminous, and heat spectrums has long ago been abandoned as quite untenable, and another, simpler and better in every way, put in its place. It is now held that the properties of refrangibility, actinicity, luminous intensity, and colour (the latter two being objective properties) are not each the results of a separate set of vibrations of the light-carrying medium, but are inherent properties of one set of vibrations of that medium.

Taking one point on the spectrum—say the yellow light of the double sodium line: the *refrangibility* is due to a disturbance produced at the surface of a new medium (prism), combined with the difference of the rate of propagation of the new set of waves set up in the new medium. This is crudely illustrated if we imagine a battalion of soldiers, which had previously been marching over a plain, to encounter a very dense forest. If the line of front be exactly parallel to the first row of trees the battalion marches through the wood in the same line as that on the plain. But if the line of front be not in the same plane, then the trees will begin to interfere with the progress of one part of the line of soldiers before it affects the other part; consequently a new line of front will be formed and a new line of march maintained through the forest different to that on the plain.

Again: the measure of *actinicity* of the sodium light is not caused by another class of waves, but is simply a property which it possesses along with the other properties of luminosity and colour—terms which go to express the effect on the retina of this particular wave-length. Example: sugar is translucent; at the same time it is sweet to the taste, and, not only so, but it is soluble in water. In like manner a particular light vibration, such as the sodium light, turns to one side on meeting certain surfaces at certain angles; it also affects a chemical preparation, disturbing its atomic or molecular arrangement. Thirdly: it at the same time produces an impression of a definite character on the retina, all these properties belonging to one class of vibrations.

Mr. Starnes' theory, so far as I have made out, is that light possesses actinicity in proportion as it is robbed or filtered free from another force—a *counter-actinic* force. Thus, red light has little action on a plate in consequence of the presence of this counter-force. Violet and blue are active because the counter-force is absent, or not present in such proportion. Mr. Starnes explains how this counter-force is eliminated in the prism. Those rays emerging to form the blue end of the spectrum have to pass through a greater thickness of glass, and are thus filtered out.

Now, taking the same diagram as used by Mr. Starnes, although it is faulty as regards the direction of the lines, I wish him seriously to consider this point:—Suppose we bring into optical contact with



the surface of the prism a perfectly-flat piece of glass, so as only to intercept the red ray, the glass to be of such a thickness as to make B C equal in thickness to B E. This piece of glass, according to known optical law, will in no way alter the direction of the ray or interfere with it otherwise. If Mr. Starnes' theory be true the red will be changed to indigo or violet; but it will be found not to change, although ten times the amount of glass be applied. Red it will always remain, which proves that its redness and want of actinicity is something else than a property conferred by passage through a certain small thickness of glass.

The fallacy of Mr. Starnes' theory may be shown in another way; but this may suffice meantime, and may cause second thoughts.

I was sorry to think that Mr. Starnes imagined he was being treated unfairly. He must give up the idea that scientific men are yet in the days of prejudice and the philosopher's stone.

He may take for granted that the fall of a theory will be no slow process, nowadays, if it fail to fulfil conditions. By the way, how would Mr. Starnes explain Nobili's and Newton's rings by his theory? G. D. Macdougald.

PHOTOGRAPHIC RESIDUES, AND THE RECOVERY OF THE VALUABLE METAL THEREFROM.*

[A communication to the London and Provincial Photographic Association.]

In selecting the subject for the lecture you did me the honour to request me to deliver before this Society this evening, I have chosen one to which I have given considerable attention for the past thirty years; so, without further preface, I enter into practical working.

Furnaces and Appliances.

When possible, it is best to construct a fire-brick furnace. This is not a difficult matter. Dig a pit about six feet by three feet, and three feet deep. Lay a foundation of brick three feet by two feet at one end; on this form the ashpit of the fire, twelve inches wide, fourteen inches from back to front, and four bricks high laid on their sides. This, with the fireclay luting or cement, makes it about eleven inches high, of course open in the front. Over the front lay a plate of iron five and a-half inches wide, twenty-one inches long, and three-eighths of an inch thick. Lay across the pit, at back, an inch bar three-eighths of an inch thick. You will now have an opening of twelve inches between the iron edges; on these the loose fire-bars are to rest. Now build up the furnace, twelve inches by fourteen inches, to the level of the top of the pit, putting an iron bar five inches by three-eighths of an inch across the pit at the top of the furnace, and also another bar, two inches above the level of the fire-bars, as stays to the front of furnace.

For the chimney remove some earth behind the body of the furnace, twelve inches deep from top, fourteen inches wide, and eighteen inches long; in this excavation form the throat of the chimney of fire-brick four and a-half inches square, the top being four and a-half inches below the top surface of the furnace. At the end raise a chimney nine inches square inside for two or three feet, where insert a damper-plate, then contract gradually to a height of twelve or fifteen feet. The upper portion of six feet may be a stout four-inch flue-pipe. Next fill in the sides and back with pieces of common brick and dry earth; and, with an iron cover in two parts and a grating over the pit, your furnace is complete at a cost of about £3. Other furnaces are built on the floor level, as my own, with a hood for carrying off fumes from chemical operations; then there are portable furnaces of fire-brick cased in iron, and, lastly, the extreme of portability is reached in the gas furnace. These latter are very convenient for trial reductions of small quantities, but when using a No. 6 clay crucible, which is a very moderate size for reductions, the pit furnace will be found the cheapest form of all; next to that the iron-cased fire-brick. Such an one also forms an excellent appliance for keeping the workroom warm. Their cost is from £4 to £6 to take a No. 6 pot. For fuel use gas coke. Select the dense light-coloured grey-looking; reject all the spongy, black pieces and all dust. Break the hard, dense pieces into such sizes as will pass readily between the pot and sides of the furnace. To prepare the furnace for use:—Place in the centre of the bars a fireclay stand or piece of fire-brick about two and a-half inches thick; on this, for special precaution till experience in firing is gained, place a skittle-pot stand easily fitting the bottom of the crucible. This will protect the bottom against currents of air through hollow places in the fire near the grate Now place plenty of wood all round the stand, also a light sprinkling of coals and some of the softer coke; light it and let it burn up gradually. Let the skittle-pot stand, crucible, and cover, in the meantime, be placed, mouth downwards, over the cover of the furnace, a little apart, to allow the hot gases to gradually dry and heat up the pot and stand. By this time the fire will need attention. Put on a three-inch layer of broken coke, on that put the skittle-pot stand, still mouth downwards, the crucible on the top of that, and cover up the furnace. They will now advance gradually to a low, red heat. Shift the crucible to one corner of the furnace, and the stand to the opposite corner. The tongs must always be heated up before touching the crucible. Clear away the ignited fuel from over the solid stand and place the open stand on it, in it the crucible, now mouth upwards, and place on the cover. Consolidate the fire with the poker and fill up all round with fresh coke, ramming with the poker as you proceed till it be level with the top of the crucible. Partially close the damper so as only to keep the fire at a bright red heat. The crucible is now ready for its charge after glazing. To do this throw in a few lumps of borax; when this has swollen up to a spongy mass take the iron stirrer (never use the poker) kept solely for the crucible use, and rub it all over inside of the red-hot crucible. We will now leave this and retrace our steps, and consider the collection and preparation of chloride of silver.

Chloride of Silver.

The precipitation and collection at the present time is mainly from the print-washing waters. These are best precipitated with commercial hydrochloric acid; this in a weak solution has no solvent power over the chloride of silver, nor does it add materially to gravity. Common salt, as usually employed, is objectionable on both grounds: the precipitate does not subside so readily when it is employed, and, being a cheap substance, unthinking operators usually add ten or twenty times more than is needed for the purpose, and thus increase both evils. For the receptacles of the washing waters conical jars in stoneware, with the greater diameter at the bottom, are to be preferred to all others.

After each addition of washing water and acid it is vigorously stirred and left to subside. Then, on clearing, a glass, developing cup, or measure is dipped in to obtain a sample, a drop of hydrochloric acid added, and if there be no opalescence produced the clear solution can be decanted by tipping the jar, or syphoning off; or an upward filter syphon may be employed, such as I introduced about 1863, a description of which will be found in the journals of the time.

This goes on till a considerable deposit is collected at the bottom. The jar should now be filled up with clean water to take up any foreign salt or excess of acid, and when clear pour or draw off as close as possible; pour the residue on to a shallow dish, and place in a warm, suitable place to dry off, if it be intended for furnace reduction.

Methods of Reduction, Wet and Dry.

The wet is as follows:—Instead of pouring the thick residue from the jar into a shallow dish, let it be placed in an open-mouthed jar, into which place a small porous pot such as is used for voltaic batteries; or, in the absence of a porous pot, procure a bladder, and fill it with weak acid solution, into which is inserted a plate of zinc with a copper wire attached. To the other end of the wire attach a plate of silver (an old spoon will do), and leave it undisturbed for twenty-four hours. By this time the chloride will have been reduced to the metallic state. The zinc remaining, porous septum and plate of silver is removed, and adhering particles of silver washed off. The silver is now transferred to a larger vessel, and repeatedly washed till a sample of the clear solution gives no precipitate or cloudiness on the addition of a solution of carbonate of soda. The liquid can now be finally drained off, and the precipitate dried for sale or use. If for sale, it had better be put into a borax-glazed crucible, with about five per cent. mixture of dry carbonate of soda and nitrate of potash, melted, and poured into the ingot mould.

The Dry or Furnace Operation on Chloride of Silver.

Process A.—The thoroughly-dried chloride of silver is mixed with powdered resin in the proportion of two parts of the chloride to one of resin, passed through the fine sieve two or three times, then well packed in the crucible, and submitted to a low red heat. In the decomposition of the resin, its hydrogen in immediate contact with the chloride of silver reduces the latter to the metallic state, the hydric chloride passing off quietly, leaving the silver mixed with some carbon. The whole is then turned out on to an iron plate to cool, the crucible immediately returned to the furnace, and a mixture made of two parts dry carbonate of soda, one part nitrate of potash, and one part dried borax. To these add sixteen parts of the silver and carbon mixture, passing all through the 36-hole sieve to thoroughly mix. The crucible should now be of a bright red heat; ladle in and allow each ladleful to deflagrate and partially fuse, and so continue until the whole is added. Now see that the fire is well poked down, the coke close in all round the crucible, and the furnace filled up to the level of the top of the crucible. Put on the cover and gradually increase the heat of the furnace to the yellow-white heat. After five to ten minutes of the strong heat remove the cover, stir up the contents of the crucible, and on withdrawing the stirrer gather up on its end a portion of the flux floating on the surface and examine it. If it be speckled with small beads of metal give it a gentle stir round, and allow it to subside a few minutes longer; then gather up a fresh portion on the end of the stirrer. This time it will most likely be practically free from beads of the metal. Check the draught of the furnace. With the hot tongs grip the crucible on the opposite side to the lip; then steadily pour out the contents into the ingot mould, which must be perfectly dry and warm, and rubbed over with chalk. Have ready to hand a light wire hook to scrape out the crucible if necessary. The pot can now be put on one side, as it is not worth risking another reduction therein.

Process B.—The chloride must be quite dry, and the crucible prepared as before directed. Take three parts dry carbonate of soda, four parts dry carbonate potash, three parts carbonate of calcium, and a-quarter of a part of fine white sand. All these must be very dry and intimately mixed by passing through the sieve two or three times. Take an equal weight of this mixed flux and the chloride, pass them through the sieve for thorough mixing, and then place in a bowl by the side of the furnace. The crucible should now be of a bright, cherry red heat. Introduce a small ladleful into the pot, and allow all effervescence to pass off before introducing a further quantity, and so on until the crucible is about two-thirds full of a semi-fused magma. Now cover the furnace, and allow the heat to rise to the yellow, occasionally looking in the furnace to see that the fire has no open channels through it, and that the contents of the crucible are in quiet fusion. On stirring it the contents should feel very limpid, and on withdrawing the stirrer it should have a thin coating of flux, not showing the slightest bead of metal. The contents may now be poured out as in the A process.

Sensitive Paper Cuttings.

The best receptacle for these is a basket; if any are put in wet or damp they will dry. Let this not be a place to throw in all kinds of rubbish, as every pound weight of such will cost you at least half-a-crown in firing, flux, and time. It is not at all unusual to discover in the ashes sent to the smelter burnt nails and screws, portions of scissors, parts of brass hinges, zinc, and lead. Of course this more than useless rubbish makes up a weighty parcel: but rest assured that you cannot have that separated from the silver except at considerable cost. Having collected a batch of silver paper it is better to reduce it to ashes periodically, in case of accident from fire when stored in large quantities. One pound weight of dry cuttings yields about one ounce of ashes of a light drab colour. If burnt in thick, compressed portions, or with insufficient air for combustion, the ash will be more or less black; the blacker it is the more flux will have to be used, and, consequently, larger pots, more fuel, and expenditure of time. For small parcels of cuttings an old iron tray (or sheet of iron) may be used. Place a row of bricks round on edge, and lay some iron rods across to make an *extempore* grating. Select a place to burn without strong currents of air. Under a wide open chimney is best, or in the open air on a calm day. Lay the cuttings lightly on the rods, and continue to supply gradually. Collect the ashes to one side occasionally as they cease to show any ignited portion, then press them down tightly. I will now suppose that one pound in weight has been obtained. Mix with that quantity six ounces nitrate of potash or soda, eight ounces dry carbonate of soda, and six ounces dry carbonate of potash. Grind the whole together in a mortar, which will greatly reduce the bulk of the mixture, and if it be a sample of ash free from rubbish the quantities will give a fluid flux with a moderate yellow heat. If useless waste paper, cards, kaolin, &c., have been burnt with the cuttings proper, it may take double that amount of flux to produce a sufficiently fluid state to allow the fine particles of silver to subside; hence the necessity for keeping your residues as clean as possible. Having consolidated your mixture of ash and flux pass it through a fine sieve. Portions of pins, nails, &c., however few, should be thrown on one side; for bear in mind the value of the metal recovered will be according to its freedom from alloy. The crucibles prepared as before, and of a dull red heat, is now filled up to within an inch to the top; keep the fire about the same red heat until you have got in the full charge. The mixture commences to scintillate quietly, the oxygen of the nitrate combining with the carbon, and traces of common metal escaping the sieve. When this sparkling has discontinued press the now doughy mass down with the stirrer and fill up the crucible again, not allowing the temperature of the fire to rise. Repeat the operation for the third time. The crucible contents, after the third pressing down, may be about half full; raise the heat gradually, occasionally stirring the contents of the crucible, and be very careful as it liquefies that no fuel falls into the molten flux, or it will most likely boil over. Always have an inch iron cold bar at hand to plunge into the flux, so as to reduce the temperature in case of a sudden boil up. The heat is to be kept up till the contents of the pot settles down to quiet fusion, and until a sample of the flux brought out on the stirrer shows no signs of beads as large as a pin's head. Then shut on the cover of the furnace and get up the heat to full yellow for ten to fifteen minutes, when it will be ready to pour as before directed.

Hypo. Fixings.

Precipitating Method.—Use a jar such as has been described for washing of prints and other nitrate solutions. Prepare a stock of concentrated solution of crude potassium sulphide (liver of sulphur) in a stoppered Winchester. Have a small cup of about an ounce capacity, and add one measure to (say) three gallons of fixing solution; stir up the solution vigorously, and the precipitate will most likely have a medium brown colour. Let it subside a few hours; then take a dip of the clear solution in the cup, and, dipping a glass rod into the concentrated sulphide, let one drop fall into the cup. If a thick, dense brown precipitate falls add another measure of sulphide to the bulk; stir again, and allow to subside. If on again testing the clear solution you only obtain a clear brown stain the metal is all but thrown down; add only a drachm of sulphide, and test again. After an interval for clearing, the precipitate will now exhibit a brownish-black colour, and the clear solution will be limpid like water; if yellow, it would be a proof of excess of sulphide, which is to be avoided—gold being partially soluble in such a solution. Having proceeded in this way, there will be no unpleasant smell; and if the fixing be conducted on the system I have indicated elsewhere the quantity of sulphide can be put in at once, and only one testing needed.

The clear solution is decanted or syphoned off, as in the case of the chloride, when sufficient precipitate is collected at the bottom to make it advisable to clear out on to a shallow pan after the washing away of soluble salts. The precipitate is then dried off in an oven or on the top of the furnace at a strong heat, and preserved till a convenient time for reducing. There are other processes, but they are far inferior. One is to keep scraps of zinc in the fixing solution vessels; the metal is a long time going down, and is complicated with zinc. The fixing solution containing silver can also be reduced to the metallic state by electro-chemical action, but, after so many years' experience, none of the many methods proposed from time to time give so little trouble, nor do they work so perfectly, as the sulphide precipitation. When properly carried out as indicated above there is no annoyance whatever from unpleasant smells. If any sulphur have been deposited from the addition of acid to the hypo. or from long exposure to the air, the sulphide of silver will have in admixture free sulphur. It will then be advisable to expose such mixture on a roasting dish—a shallow fireclay saucer—at a low red heat, the furnace top being brought off so that the air has access. The free sulphur will then burn off with its characteristic blue flame. Now take (say) one pound of the roasted sulphide of silver; add about seven ounces nitrate of soda, four ounces dried borax, six ounces dry carbonate of potash, and half-an-ounce of fine sand. Mix in the mortar, and pass through the sieve once or twice; put it into a bowl, and place near the furnace so as to be convenient to ladle into a red-hot crucible, a small portion at a time, allowing deflagration to subside before adding further portions. Finally: raise the heat gradually to the yellow stage, stirring occasionally, and, when calm, fusion has set in; cover the furnace and keep up a strong heat for fifteen to twenty minutes. Make examination of the flux for beads, and if free from such, and the flux on breaking exhibits a glassy fracture, the contents may be poured into the ingot mould. This metal (if from gold-toned prints) contains gold, and should therefore be kept separate for parting assay, otherwise it is best to combine the separate ingots from the pot into one bar for single silver assay.

Spent Gold Toning Baths.

Collect these in conical glass vessels—precipitating jars. Such vessels are obtainable holding about nine pints, or as small as assay flasks of one or two ounces. First acidify the solution with sulphuric acid, then add about half-an-ounce of hydrochloric acid to the gallon. Next prepare a saturated solution of sulphate of iron; add gradually, stirring with a light, smooth rod of wood until no further cloudiness is observed on looking through the glass. Allow the solution to stand at least twenty-four hours, then add a drop or two of iron solution to the now bright solution, and note if it produce any cloudiness. If so, add more sulphate of iron solution, stir up, and allow to subside again. As the precipitate is very valuable it may stand for two or three days to collect the finer particles from this high-gravity solution. When so subsided decant very carefully, and then fill up the vessel with water rendered acid with sulphuric acid; a few hours will now be sufficient for subsidence. Decant again and repeat three or four times, reducing the quantity of acid each time, the last being plain water. Collect the precipitate in a porcelain dish or crucible, and dry off in an oven; the result is a mixture of metallic gold and chloride of silver. Melt in a small smooth crucible, called "assay gold pots," with a portion of the flux recommended for the reduction of chloride in process B. Do not neglect to first glaze the pot with borax. Leave the button of metal in the pot till cold, then break off the button to obtain it; clean and weigh. Now take three times its weight of metallic silver from your other reduction, melt together in a plumbago pot, and pour the melted metal, as soon as liquid, into a pail of water; collect the granulated metal, and wash with distilled water. Then dissolve in dilute nitric acid by the aid of heat; the gold will be left as a rich brown powder, which has to be washed after decanting the acid nitrate of silver solution. It is then boiled with a fresh portion of nitric acid, and again well washed, testing the washing to see if any silver be contained therein. Finally, dry for sale or use.

Gelatine Emulsion Residues.

I have r[illegible]d two methods for extracting the silver from gelatine solutions. I[illegible] [illegible]king on batches of six to ten gallons contained in chemical stoneware pans the solution is made strongly acid with hydrochloric acid, and zinc plates placed therein. I now pass into the mixture steam at about twenty pounds' pressure to boil up rapidly, and continue the boiling for at least twenty minutes; the bromide of silver is thereby converted into metallic silver, which is allowed to subside. For small quantities I warm up the solution, dilute considerably with water, and add some hydrate of soda solution, then hyposulphite of soda to dissolve the bromide, and so obtain a clear solution. The silver is now precipitated with sulphide of potassium, and collected as directed under hypo. fixings above described. F. W. Hart, F.C.S.

A FEW NOTES ON CANARY MEDIUM.

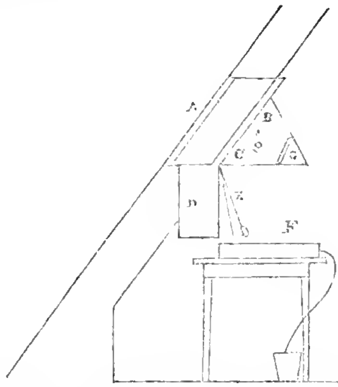
[A communication to the Edinburgh Photographic Society.]

Some time ago your Secretary gave me some of the canary medium, and asked me if I would try it and give him the results at which I arrived.

The sketch I show you will explain the kind of room and light with which I have to work. It is a small room, twelve feet by nine feet, lighted from the ceiling, which at one side slopes from near the floor. The window is two feet six inches by one foot six inches, and I fitted a box below it open on the top, and faced with the canary medium to give me a light directly in front when developing. This box has a shutter of brown paper stretched on a frame to cut off as much light as is wished. The window has also a frame fitted to it, which is put up with four buttons, and it also has a brown paper shutter to regulate the light.

As my window faces the east these shutters are necessary when the sun is bright I put on the frame (B) three thicknesses of the canary medium; these I oiled in the same way as was usual with the ruby paper. The flood of light was very great—so much so that your Secretary, when he came into the room, made the remark—"What white light!"

By drawing the cord to the shutter (C) I can make the room as dark as I please. After closing this shutter I selected two plates—one a Fry, the other a Bennett—and proceeded to make transparencies from two negatives selected.



A Window, two feet by one foot six inches. B Screen, canary medium. C Brown-paper shutter, movable at will. D Box to throw down light in front of developing tray. E Brown paper, movable at will. F Washing trough. G Printing-frame exposed.

I then let the shutter (C) drop right down, so that the full flood of light came upon the plate. The light at this time was so strong I could see a pin on the floor nine feet from the window. These two plates I now show you. They are *quite free from fog.* The developing dish was on the table two feet six inches below the window, and the plates were frequently lifted for examination. I then proceeded to make another transparency from a rather thin negative, placed it at a distance of ten inches from the frame with the same light as before, and exposed it for five minutes, the result being a pretty fair picture. From this it was clear that, however well a plate might be developed at a distance of two feet six inches from the window, the light was far from being a safe one to trust too much. I then removed the oiled paper and substituted two sheets of the paper unoiled, and exposed another plate for five minutes, the result being a *very faint* outline of the portrait. I then oiled one of these sheets of paper and exposed another plate for five minutes in the same way as before, and in this case got much more detail. From this it would appear that two sheets of paper is the quantity required for a light directly in front; while one sheet oiled and one unoiled, if the direct light be cut off by the shutters, as I use them, give a very pleasant and safe light to work by. I found even the two thicknesses of the canary medium gave a much more comfortable light to work by than the old ruby, which was so very trying to the eyes. I intended going over these again, giving an exposure of three minutes, but the weather being dull I had to give it up, though I hope to have another opportunity before long. THOS. H. W. KNOLLES.

SHORTCOMINGS OF PHOTOGRAPHY.

[A communication to the Dundee and East of Scotland Photographic Association.]

IN photography, where so much depends upon manipulations and processes, technicalities require, and do actually receive, great attention. The vast majority of papers read and discussions held at photographic society meetings are upon technical matters; and while a great deal has to be done yet before our formulæ can be considered perfect, or apparatus all that could be wished for, I think the time would be well spent were we to leave these well-worn grooves occasionally, and, taking a broader view of the situation, consider in what precise direction improvement is most urgently required. This idea was forced upon me the other day when, having the opportunity of comparing a photographic landscape with an engraving taken from the very same spot, I had to confess that the photograph lacked in a woeful degree the breadth and fine pictorial quality of the engraving. Nor was this due to any liberties which the artist has taken to improve his picture at the expense of truth, as could easily be seen by referring to the photograph. What, then, constituted the difference? and why was there a fine breadth of effect in the engraving, and a particular absence of it in the photograph, when, in both cases, the very same subject had been chosen?

In the following remarks I shall give what appear to me to be the principal shortcomings in a photographic picture; and as the subject is both wide and difficult, I make no pretenson to do more than skim the surface. To be concise, and at the same time intelligible, I will consider the subject—1st, as to outline; 2nd, as to light and shade; and 3rd, as to colour.

1st, as to outline: A design, whatever it may be, is forcible in proportion as it is simple. An artist secures breadth by seizing the salient points and presenting them unbroken by paltry detail. For this reason the photographic outline is too complex to be effective. It must be remembered that, while it is so far a copy of nature, it is a very diminutive copy, and will not bear the same elaboration as the original. Besides, seeing that objects in very different planes have to be adequately represented on the flat as being at different distances, some plan must be devised to do this. One of the most important aids in this direction is the surpressing of outline here and there, and the simplification of it where it cannot be surpressed. In this way a foreground may be made to come forward, while the distance seems to retire. Of course the camera has no such modifying power, and although we often see in the photographic picture an outline which would be better softened, or another accentuated, we have no way of photographically effecting it.

This equally intricate outline over the whole length and breadth of the picture not only destroys distance but it is not a correct representation of what we see; for it will be found, if the eye be fixed upon a certain object, that the outline grows less and less intricate as it nears the margin of our view. Looking along an avenue of trees, for instance, with our eyes fixed upon a certain point, although we have a vague, general impression of the trees immediately on our right-hand and our left, we do not distinguish every little leaf and every little spray as the photographic lens reproduces them. If the eye were in focus at one and the same time upon an object a few feet in advance, and upon another half-a-mile away, our perception of distance would not be nearly so perfect as it is, and yet depth of focus in a lens is considered a very important feature.

It may be asked, then, if our pictures ought to be blunt or blurred towards the margin? By no means. The impression which the eye receives of objects not precisely at the point of sight is not a blurred image. The general impression of outline is perfectly sharp, but the eye cannot follow it in all its little tortuosities. If an artist would be successful in conveying the impression which a certain scene had upon him, he must manage to bring the eye to rest upon his canvas precisely where his own rested when the original impression was produced. He does this by carefully working up from simple forms at the margin to the most complex at the point of sight. In this way the eye is carried forward to the focus of the picture, and finally chooses as a centre the very spot which was the centre of his own impression. I cannot see how the photographic outline, which is as pointed and precise at the margin as in the very eye of the picture, can lead one on into the distance; rather, I should say, is the attention arrested and fixed by what should have been only a stepping-stone. The point of maximum interest is never at the margins of my field of vision, and yet I have frequently seen it here in photographs. Vignettes have always been considered the most artistic of photographic productions, and this, I am convinced, simply because their margins are robbed of their undue importance. To recapitulate, then, I consider that the photographic outline, being equally intricate throughout, by scattering the interest robs the picture of the charm and force of one common centre.

With regard to light and shade: I consider they are not true to nature rendered by photography. Examine even the very best photograph, compare it with what you see in nature, and you must confess that the amount of black in it is far in excess of what you ever see in broad, beautiful daylight. Cast your eye over a landscape and note that three-fourths of the whole is in half-tone, the other fourth divided between high light and deep shadow. Photograph the same landscape, and you will find a very different proportion. A tree trunk or a large boulder, innocent of black so far as the eye could see, comes out with shadows "tartarian" in their depth. Let the light fall off so little that the eye can scarcely appreciate the shade at all, the sensitive plate will render it fourfold. The camera and the eye do not value light by the same standard at all; we judge by its luminosity, the camera by its actinic force—hence the confusion. Here we have a soft, delicate shadow, apparently only a little less intense than the high light; unfortunately, being reflected light, it has not actinic force in proportion to its apparent luminosity, and is rendered in the photograph as being many times blacker than it seems to the eye. But not only in individual parts does this hold good, for the whole general tone of the photograph is lowered from the same cause. Those who practice landscape photography must have noticed how equally luminous the landscape and sky at times would appear to be. A photograph of the scene, however, represents the earth as many times blacker than the sky, and, whereas in nature the distant hills melted imperceptibly into the clouds, there was in the photograph a line of demarcation painfully plain.

To recapitulate, then: since we judge of light and shade by degrees of luminosity and the sensitive plate by actinic value, and since shades are often luminous without being chemically active, I consider that light and shade as we see it is so far not correctly rendered in a photograph.

But photography has still another important shortcoming. I refer to the erroneous colour values which it gives us. I have already suggested that, as a mere matter of light and shade, the falling off of actinic force, even in feeble shadows, is out of all proportion to the falling off of its apparent luminosity. I have now to go a step further, and remind you that, in the matter of colour, of two tints the brighter to the eye may be rendered the darker, and the darker to the eye come out the brighter. This is an entire reversal of our sensations, and I need scarcely point out how serious a fault this is. To be utterly false to nature is bad enough; but were we left the same range of contrasts, even if they were erroneous, our pictures might still be beautiful, as witness many charming effects in portraiture where, although the various tints of the subject are erroneously given, the error is as often on the side of heightening contrast as reducing it. In landscape work we are less fortunate, for the prevailing colours in a landscape being various tints of yellow, brown, or green, all of about the same actinic value, we entirely lose the beautiful contrast which we see with our eyes.

Not only does the picture suffer in artistic effect from this, but should it happen that two objects of about the same actinic value lie side by side, no matter that one is orange and the other a dark olive green, they will be run together, and probably in many parts be indistinguishable from each other, thus introducing an element of great confusion. I was very much struck by this some time ago, photographing at the Gannseley, near Breebin. To look up the water from the bridge the scene was beautiful. A few large boulders at the edge of the stream were the darkest objects, then the wet banks only a little lighter, then the dry earth above in still lighter tints of red and brown, above that dry grass strewn with withered leaves, and, last, the trees —everything from light yellow to deep sombre olive-green. I was considerably disappointed, on printing from this negative, to find that to distinguish this tree from that, or to discover where rocks terminated and banks began, I had to hold the print within four inches of the eye. There were no beautiful contrasts—indeed, a few feet away it was difficult to make out the nature of the subject; beyond that there was a sky, and something white (water perhaps) running down the centre of the picture.

Having gone over what appears to me to be some of the principal shortcomings of photography, I may, perhaps, be allowed a few words as to how these faults are to be expurgated.

In the first place, I am convinced myself that "gelatino-bromide" has done nothing for us artistically; on the contrary, I am quite sure that the various shade and colour values were more correctly given by collodion. I would not for this reason resort to collodion, but would rather hope that very soon we may be able to prepare plates exceeding gelatino in rapidity and collodion in quality.

Certainly *the* improvement which we stand most in need of, as far as the chemical department is concerned, is the introduction of a plate giving us colours rendered correctly in black and white according to their visual values.

With regard to the excessive amount of detail: I would obliterate much or little of it, according to circumstances, by printing upon paper with a proportionately rough surface. Small pictures to be viewed in the hand, since breadth is not of so much importance, could be printed upon a moderately-smooth surface; while large photographs, intended for the decoration of walls, requiring breadth and force, and where detail to an excessive amount would be out of place, would be better printed upon rougher surfaces.

With regard to the intensely-black shadows: I would obviate that by using a printing process capable of printing only to a certain depth.

I need scarcely say that this would exclude albumenised paper. A determined effort should be made to throw off the trammels of the vitiated taste brought about by albumenised paper pictures. We have been so long used to the pure high lights and deep black shadows that a picture with less spice in it (so to speak) is apt to strike one as wanting in contrast, or to have a washed-out appearance. This impression would very soon wear off, and I have no doubt but that then we would recognise how violent an effect is produced by printing upon such a surface. With regard to the fine contrasts which we lose from non-actinic colours in nature: I see no other way than to add them by hand.

I saw it mentioned in the photographic journals, not long ago, that on the continent, in copying works of art, correct colour values were added by skilled artists. Of course if it be necessary to do so in copying paintings, it is just as necessary in photographing from nature. I have tried the plan of covering the back of the negative with tracing-paper, and working upon that with a pencil and stump. So far I have not been successful, the parts added being distinguishable in the print. More recently I have produced enlarged negatives from small transparencies, using "gelatino-bromide" paper. There are more successful and most effective alterations which can be made either with colour or pencil. The negative, even after it is waxed, is not not nearly so transparent as glass, and the shadows do not print to such a pitchy black, giving thereby a truer effect. The very slight grain of the paper is rather an improvement than otherwise, especially in large pictures.

J. K. Tulloch, M.D.

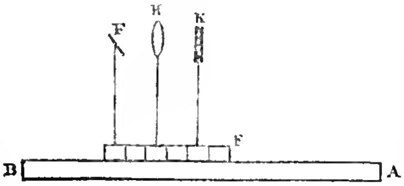
MISCELLANEOUS SUBJECTS.

Photomicrography in Lucerne.

Dr. Stierlin-Hauser, of Lucerne—an accomplished Swiss chemist and man of science, and the landlord of the largest mountain hotel in this country, the celebrated Rigi-Scheideck—is also an expert at photography, and well read in the English and foreign literature of the subject. Some time ago he was public analyst to the city of Lucerne. The manifold functions just stated are characteristic of Switzerland, in which your hotel landlord may be a doctor of philosophy and one of the local magistrates, professional and other kinds of life being here very much "mixed," and open to everyone provided he be but properly qualified. The affix of "Hauser" to Dr. Stierlin's name is the maiden name of his wife, according to a somewhat prevalent custom in Switzerland, in which the individuality of the wife is not so completely publicly lost in that of the husband as in England.

Much of Dr. Stierlin-Hauser's attention has been devoted to microscopic photography, and the following is his plan of operations:—A, B, *fig* 1, is a thick piece of board about a foot long, with a slot in its upper surface in which rectangular blocks of wood slide, and can be fixed anywhere along the slot. Brass stems to carry lenses, reflectors, and so on fit into holes in the movable rectangular blocks, and the necessary firmness is given where desired by means of thumb-screws.

FIG. 1.



On one of those days of unbroken sunshine which are so numerous here—far from the sea, and south of the champagne-producing districts of France—the board is placed outside the window, and the rays of the sun are reflected by the mirror F through the lens H, and the piece of cobalt-blue glass K. Thus a powerful beam of blue light is available for use in the operating-room, the rays being brought to a focus on the object by the selected position of the lens, or rendered more or less parallel at will. By means of the blue light any optical trouble as to non-achromatism is abolished sufficiently for practical purposes.

Inside the room the blue beam is received upon a mirror a few inches from any transparent object to be photographed, and thrown obliquely upon it, to get the best effects of light and shade. The object is then photographed in the ordinary way, a microscopic objective being used in place of the ordinary camera lens. Much depends upon the quality of this lens, for it must be aplanatic, and it is not every maker who can turn out good microscopic objectives of this class. Dr. Stierlin-Hauser has six objectives no good for the purpose; those two of his which answer admirably were made by Herr C. Zeiss, of Vienna.

When an opaque object has to be photographed it is placed horizontally, and the objective directed downwards upon it. By means of a prism above the objective the image is deflected at right angles, and falls, as before, upon the plate in the camera. All the parts between the objective and the plate are enclosed, so that no diffused light can enter the camera.

The difficulty mentioned in the last British Journal Photographic Almanac, about obtaining equal sharpness for those parts of an object which are at different distances from the lens, Dr. Stierlin-Hauser largely overcomes by giving about $\frac{1}{30}$ of a turn to the screw of the objective during the exposure of the plate, so that the lens is slightly moved during the operation. With sunlight and a slow plate, Dr. Stierlin-Hauser finds the maximum time of exposure to be seven or eight seconds. With low powers the minimum exposure is a second and a-half. By this system the operations are much like those of ordinary photography, and the operator works with comfort in full daylight.

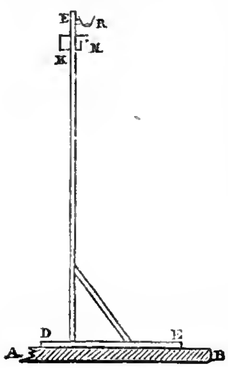
A photographer published, some time ago, that at recent photographic exhibitions there was more apparent halation in enlargements than was probably due to reflection from the back surfaces of the plates, and suggested the future use of lenses better corrected for the chemical foci. If light filtered through cobalt-blue glass were to be employed with ordinary enlarging lenses, and Professor Stebbing's film were used instead of plates, I suggest that there would be a great improvement in the quality of enlargements. I have been trying experiments with those films (and hope to publish the results shortly) upon test objects in which halation exists where not suspected when plates are used, and found the films to give a correction to the error unobtainable by the backing used for plates; but I wish to give the results of trials of the films as a whole, and to avoid premature publication.

Photography by the Magnesium Light.

Some experiments have been recently published on the use of bottles of oxygen in which to burn fragments of magnesium riband, to take portraits by the magnesium light. An objection is the trouble and cost of making the oxygen, and that means have to be adopted to to diffuse the light near its source. The objection to burning the riband in air is that the exposure is longer, and the burnt ash has a tendency to drop off and put out the light before the selected length of metal is consumed.

Some years ago I had occasion to use the magnesium light by night, and overcame the difficulties by the adoption of one part of the principle of Larkin's magnesium lamp. The method may be explained by the aid of *fig.* 2, in which A B is the top of a firm and solid table, on which was placed the base-board D E, supporting the wooden upright F D, which was some seven or eight feet long, consequently reached nearly to the ceiling of the room. R was a kind of little brass funnel with no neck, and a large opening where the neck should be. This brass-inverted cone was no larger than an egg-cup, and its lower opening was about as large as a fourpenny piece. K is a tin spirit lamp, with a horizontal neck and flame at N, so that anything falling through the funnel must pass through the flame, yet just miss touching the wick. The combustible substance was magnesium powder mixed with sand. One thimbleful of the powder, for instance, is mixed with two of sand with a spoon or bit of wood on a sheet of paper; then, the sitter being in position and all being ready, the mixture is poured all at once into the funnel. A long sheet of flame of one or two seconds' duration is the result. If the picture prove over-exposed the proportion of sand has to be increased in the next trial, and that of the magnesium powder correspondingly diminished. When once the right proportions are known portrait after portrait can be produced, properly exposed with dead certainty. No cap is necessary to the lens, provided a candle only be used for the normal illumination of the room, and it be not placed so that an image of it can be thrown by the lens into the camera. The proportion of magnesium powder regulates the proper exposure.

FIG. 2.



At first there was a difficulty, and one only, with this simple apparatus, and that was that the aqueous vapour from the flame condensed on the lower parts of the brass cone, and the powder stuck to the neck of the wet funnel, sometimes blocking it and arresting the flow of illuminating material altogether. The neck of the funnel was therefore cut off, and the lower opening of the cone made rather large. It would be an improvement to use something on which aqueous vapour has less tendency to condense than upon cold brass. The brass, however, was subsequently kept hot by fixing the spirit lamp nearer to it than in the first experiments.

The larger the proportion of magnesium in relation to the sand the longer the flame and the shorter its duration. With a very rich proportion I once had a flame seven or eight feet long, reaching the baseboard and burning its surface. The long flames give the necessary diffusion of light, and a white sheet on the opposite side of the sitter improves the shadows. The finest artistic effects of light and shade on the countenance of the sitter can be obtained by this method when the tall wooden lamp is placed in the proper position.

The sitter need not be fatigued with focussing operations; a candle placed where his face will come will do to focus upon. In fact, it is a capital method for the comfort of the sitter, who must not look in the direction of the coming flame, lest his eyes be dazzled by its magnificent flash, which, however, lasts but a second or two.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Society, held on the 16th inst., the chair was occupied by Mr. A. Haddon.

The evening was the monthly one on which a "lecturette" is given, and on the present occasion Mr. F. W. Hart discoursed upon the subject of *Residues* [see page 120], and illustrated his remarks by experiments and demonstrations. At the conclusion of the lecture,

Mr. W. M. AYRES asked whether it was not better to use engineers' coke rather than the ordinary gas coke, and whether it was not better when treating sulphide to burn off acid with nitrate of potash.

Mr. F. YORK said that he had been in the habit of reducing his residues himself, and of recovering fifty per cent. of the metal used. In order to test the matter he had recently divided a bulk of residue into three portions—one of which he had reduced himself, the other two having been sent to different refining houses—and compared the result. He found that the result was about the same in money value in all three cases, but on examining the flux left there was evidently silver contained in it; indeed, it proved to be worth about ten shillings per pound. The danger of not effectually and thoroughly performing the reduction was one which those who were not engaged in it as a business should guard carefully against, or they would lose rather than gain after all their trouble. The average value of dry chloride of silver or of paper-ash well burned he found to be one troy ounce of metallic silver from three avoirdupois ounces of residue. Sulphide of silver yielded rather more than one-quarter its weight of metal. For the precipitation of the chloride from print washings he kept two paraffine tubs, with taps about half-way down. When one was filled the other was taken into use, and before that was filled No. 1 would have settled down clear, and the liquid could be poured away. He would ask whether there was any advantage in using borax when fluxing. Like Mr. Ayres, he thought it much better to use steam coke, and did so accordingly.

Mr. A. COWAN inquired whether there was any advantage in using salt in flux.

The CHAIRMAN said that he used coke of both kinds. When the residue was very refractory and contained much alumina he used oven coke.

A Member suggested the use of hard carbon for getting greater heat.

Mr. HART, in replying to the various questions that had been asked and remarks that had been made, said that if hard carbon were used sixty feet of chimney might be required to get draught enough. As for the amount of saving possible to effect by systematic economy and careful reducing, he thought it quite practicable to get as much heat as eighty or eighty-five per cent. Nitrate of soda was sometimes used for fluxing because it was cheaper than nitrate of potash. Soda ash and not common carbonate of soda should be used, as the latter contained so much nitrate of crystallisation that it would spark in the crucible. For precipitation he preferred hydrochloric acid to salt, which took much longer to complete its work. When treating sulphides he did burn off with nitrate of potash. When he suspected foreign matter he used borax. Borax and boracic acid have great affinity for foreign matter. The flux after the completion of the reduction should have a vitreous apppearance. If it have a dull appearance a good deal of metal is left in it. A gentleman called upon him one evening telling him that he had had a residue reduced whilst waiting at the refiner's. Having picked up a small piece of the flux he showed it to him (the lecturer), who saw at once that the action had not been complete, and on putting it into the furnace, he extracted four shillings' worth of gold from that small piece of flux. The object of using sand was that when one is reducing, and has a quantity of alkaline flux left for some time in the pot, the crucible might be attacked; the loose sand was then acted on instead of the crucible. Common salt was principally used in making assays of minerals when litharge had been added; the lead then went down in a shower.

The CHAIRMAN proposed a vote of thanks to the lecturer, which was warmly accorded.

It was announced that on the 28th inst. Messrs. C. and F. Darker would give some demonstration of, and experiments in, polarisation of light.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE ordinary meeting of this Society was held in 5, St. Andrew-square, on Wednesday evening, the 6th instant,—Mr. William Neilson, President, in the chair.

The following gentlemen were elected ordinary members:—Messrs. Daniel Finlayson, F.R.P.S., Andrew Forbes, Edward Debenham, Julius Peike, W. S. Anderson, and Hunter Muir.

Mr. T. D. POPE gave a demonstration of his mode of producing gelatino-bromide enlargements on paper. Two very successful enlargements were produced, of good colour—brilliant, yet soft. In the course of the demonstration he (Mr. Pope) said it was imperative that every attention should be paid to cleanliness and careful washing between development and fixing in order to avoid stains. While the paper is dry it is very liable to receive stains from damp fingers. He particularly recommended that the developer be poured into the dish, and the exposed paper, previously soaked in water, floated thereon face down, as the plan usually recommended of pouring the developer on the print, in his hands, tended to produce unevenness and stains. When the image was fairly visible, then it should be turned face up. In practice, he had a piece of white cardboard nailed on the wall of his operating room with the various sizes marked upon it. The image thrown on the desired space from a lantern was duly focussed to the required size; the light then being turned down, a piece of dry argentic paper was tacked on the space and the exposure proceeded with. He (Mr. Pope) preferred negatives of moderate density—not too thin, but with clear shadows. The time of exposure could only be learned by experience, the quality of negative and power of light being the chief factors. The following were the formulæ employed:—

No. 1.

Oxalate of potash	6	ounces.
Boiling water	30	,,

No. 2.

Protosulphate of iron	2	ounces.
Water	10	,,

No. 3.

Citric acid	3 ounces.
Water	10 ,,
For use, take of No. 1	8 ,,
,, No. 2	2 ,,
,, No. 3	½ ounce.
Fixing:—Hypo.	12 ounces.
Water	40 ,,

Fix twenty minutes.

Hardening bath:—Alum	2 ounces.
Water	20 ,,

Mr. Samuel Tamkin said his experience fully supported that of Mr. Pope's, in so far that greater freedom from defects resulted from floating the paper in development, and also advised that dishes only a very little larger than the paper should be employed. He handed round a large number of bromo-argentic paper prints with duplicate on ordinary albumenised paper. It was noticed that in some cases the bromide prints were the most suitable expression of the subject. In reply to questions, he (Mr. Tamkin) said that the difference in tone was due to the modifications in the developer. The cold, bluish-green tone was got by the use of that generally employed, viz:—Saturated solution of oxalate of potash, three ounces; saturated solution of protosulphate of iron, one ounce. He understood that an excess of iron caused yellowness; he, therefore, increased the proportion of oxalate, and gave a much longer exposure. By this means the prints developed as quickly as well-exposed dry plates, the colour was better, and the whites were remarkably pure. He found it of great importance to time the exposure correctly; for, though a great deal is said about the latitude allowable in this as in the working of gelatine plates, in neither should the best results be looked for unless the exposure has been correctly timed. It was in this that a thorough knowledge of the proper qualities of a negative became of value, because with such knowledge an operator might produce dozens in succession without a failure. It was always advisable to immerse or float the wetted paper face down in the developing dish, as mentioned by Mr. Pope. When small work was attempted great care was necessary in the mounting and finishing, as the surface was much more liable to injury than albumenised paper. He had found prints lose brilliancy by being burnished.

Mr. M'Kean thought the ordinary sciopticon unsuited for that work, and believed a six-inch condenser ought to be employed.

Mr. J. M. Turnbull said no advantage would be gained by a six-inch condenser for *carte* work. In fact, such a size would be a positive disadvantage.

A vote of thanks to Mr. Pope, proposed by Mr. Craig-Christie, was carried by acclamation.

A discussion on *Canary Medium* then took place, initiated by Mr. Knolles. [See page 121.]

Mr. R. H. Bow said he had found the ruby lamp too trying, and he was endeavouring to devise a substitute. The result of his experiments he hoped to embody in a paper, which he promised to bring before the Society at an early date.

Mr. Tamkin had tried the "canary," and was not satisfied with it. He found three thicknesses of pale yellow tissue paper was really better. His window was not under the influence of direct sunlight.

Mr. W. T. Bashford said that by the courtesy of Mr. Scorah, of Bradford, he had been enabled to distribute samples of canary medium to several members, and laid pieces on the table for others who might care to experiment with it. He thought that the opacity of the paper played an important part in its usefulness, as, according to Mr. Knolles, the medium was unsafe if oiled. There was no doubt, however, that the illumination was most pleasant, and with two thicknesses Mr. Knolles had shown it was quite safe, the negatives and transparencies produced being entirely free from fog. He drew the attention of experimentalists to a statement by Mr. Henderson that, though the light when examined by a spectroscope might exhibit a decided green, yet it might be quite safe for the dark room. He also noticed that some experimentalists had endeavoured to arrive at a solution of the difficulty by taking negatives of surfaces covered by various pigments. They thought that the least actinic pigment ought to indicate the safest colour, and be a guide to judge of the sensitiveness of plates. He thought experiments in that direction were likely to be misleading, and believed that pigments ought not to be compared with the colours as seen in nature; their action on sensitive surfaces was entirely different. He considered it an easy matter to produce the most contradictory evidence when the pigments of the artists' colourman were employed; but the photographer generally had to go direct to nature, and it was only by experimenting with nature's colours or their equivalents that the photographer would be materially benefited.

Mr. Turnbull exhibited a modification of Mr. Macdougald's lantern carrier, in which the parallel sides were made of metal instead of wood, thus allowing this ingenious contrivance to be sufficiently reduced in width so as to render it applicable to the sciopticon. He also exhibited Cadett's new exposure shutter.

Mr. Wardale presented the Society with a non-actinic lantern of new design for use in demonstrations.

The thanks of the Society were presented to Mr. Wardale, also to Mr. Knolles for his carefully-conducted experiments, and the meeting terminated.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

A popular evening of the Association was held in the Christian Institute, 70, Bothwell-street, on Wednesday, the 6th instant,—Mr. John Parker, Vice-President, in the absence of Councillor Robertson, in the chair. The feature of the evening was a magic lantern exhibition arranged and manipulated by Mr. Thomas Swan.

A very fine series of twenty transparencies from one negative, showing the multitude of pleasing tones which may be got in transparencies, by Mr. Alex. Cowan, of London, was very much admired.

Mr. L. Dixon, of Colne, exhibited some collodio-chloride transparencies printed by contact, most of which were very fine.

The other contributors were Messrs. York, Woodbury, England, Wilson, Lang, &c.

There was a very large attendance of members and friends, and the meeting terminated with votes of thanks to the contributors of transparencies and to Mr. Swan.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.

The usual ordinary meeting of this Association was held on Tuesday evening, the 12th instant, in the College of Physical Science, Newcastle,—Mr. A. L. Steavenson, J.P., of Tynemouth, in the chair.

Mr. E. Dodds read a paper entitled *Notes on Ruby Light*. He said that he had confined his attention principally to the testing of various coloured media suggested in the photographic journals, &c., and had decided in favour of ruby glass. He, however, showed in a lantern, brought for the purpose, several variously-coloured glasses and papers, some of which were highly suitable, the best of them being Mr. W. E. Debenham's cathedral green, combined with rag yellow paper, and a stained red glass combined with a saffron-coloured parchment paper.

Mr. J. P. Gibson observed that he used cherry fabric, but always with artificial light.

Professor Herschel said that he had nothing to offer from experience regarding the relative values of the different kinds of non-actinic colours which had been exhibited to them that evening for dark-room illumination. The non-actinic property depended so much upon the nature of the chemicals used, as well as of the light tested, that it must be in great measure a subject for experiment with different sensitive plates. But the exact measurements to which Mr. Dodds had submitted them showed very clearly that for manipulations of ordinary dry plates there was a large choice of very different-looking colours, of which several were almost equally harmless and inactive. Regarding the fatiguing effect of ruby-glass light upon the eyes: the complaint against it was, probably, in some degree well founded, as its low refrangibility must lengthen the visual focal distances of objects examined by it, so as to make it necessary either to hold such objects at a greater distance than usual from the eyes, or else to strain the adapting muscles of the eye to bring to a distinct focus on the retina the image of such objects when they are held close at hand; and especially when they are so closely examined and inspected as we are accustomed to do by holding them very near the face, in ordinary light, for minute discrimination. Short-sighted persons have a natural advantage over those whose usual sight is either normal or long-focussed in the power of minute observation; and in ruby light such persons would feel at home, or would at least be on a level of scrutinising aptitude and ability with ordinary-sighted persons in ordinary light. Normal-sighted persons, on the other hand, would feel as if the long-sighted infirmity natural to old age had overtaken them before its time, obliging them either to forgo the advantages of close inspection or to strain the focussing muscles of the eye fatiguingly to re-acquire the faculty of distinctness of sharp-focussed definition stolen from their vision by the light when attempting to enlarge the view of an object in the usual way by looking at it closely. The young generation of normal-sighted photographers will, no doubt, be led, by a prevailing use of ruby glass, to give the focussing muscles of the eye exceptional exercise in one particular direction. This will either (if over practised) tend to make them short-sighted for ordinary light, or, if only exercised enough to extend and not to displace the range of muscular efficiency, will furnish easy early training in a useful means of mitigating the usual tendency to deterioration of the eyesight; and it will prepare eyes so exercised in youth to combat more successfully than untried eyes could do the infirmity of vision natural to old age, and the defect of long-sightedness which normal eyes acquire sensibly even in the advancing years of mature life, without making it necessary then to hold a page of print at arm's length in order to see its letters clearly. A moderate use of ruby light, although somewhat fatiguing to normal eyes, must, accordingly, be rather likely to have a wholesome and invigorating than a deleterious and injurious effect upon the sight. It would be a useless light, however, for colour-blind persons; and the sense of red colour in normally-constituted eyes, it may be conjectured, would be quickened and heightened at the same time, without disadvantage, with the extended power of focus-adaptation. But a great range of other colours not ranking nearly so low in refrangibility as ruby red, it has been clearly shown by Mr. Dodds' illustrations and experiments, is open to selection and to adoption in a dark room with perfect safety by those who may be averse to suffering the feeling of inconvenience sometimes occasioned by the bright red, even if its trying effect on the eyes should be clearly proved to be not only harmless but, in reasonable limits of exposure to it, of useful service and ultimate benefit to their efficiency.

The Chairman proposed a vote of thanks to Mr. Dodds for his paper, which was carried with acclamation.

The Secretary exhibited and described a camera, sent for that purpose, by Mr. McKellen, of Manchester.

Some fine transparencies were shown by Messrs. Mawson and Swan, taken on gelatino-chloride plates of their own manufacture.

Mr. Dodds proposed a vote of thanks to the Chairman, who, in reply, expressed the pleasure it had given him to be present on that occasion. He regretted that he could not come oftener to the meetings, which, he said, were always instructive.

The second annual dinner of the above Association was held in the County Hotel, Neville-street, Newcastle, on Friday last, the 15th instant. Professor Herschel presided, and was supported by Mr. Way, Mr. Payne, Mr. Pike, and others. Mr. Garland occupied the vice-chair, and was supported by Mr. Ross and other members of the Association.

The CHAIRMAN proposed the usual loyal toasts, which were drunk with enthusiasm.

Mr. WAY gave the toast of "Photographic Art and Societies," and spoke of the value of an art education.

Mr. GIBSON responded.

The VICE-CHAIRMAN proposed "The Newcastle and Northern Counties' Photographic Association." He deprecated the art jealousies which seemed to exist among even our great men. He thought that there should be more generosity of disposition shown towards students by those who had made a life study of art. A different spirit prevailed among continental artists, from whom our native painters had derived a good deal of their knowledge of art. He trusted their Association would tend to break down the spirit of exclusiveness which prevailed, and the fear, so to speak, that their ideas or knowledge of art might be acquired by anybody else. Our countrymen in the past had experienced no such narrowness or jealousy from the old masters, and Englishmen should be more willing than they were to hand down to those who aspired to follow them all the knowledge of the art they could for the benefit of posterity.

The CHAIRMAN responded.

Mr. ROSS, in a few well-chosen remarks, proposed the toast of "The Officers and Committee of the Newcastle and Northern Counties' Photographic Association," which was responded to by Mr. Laws, Mr. Pike, and Mr. Sawyer.

Other toasts followed, and the proceedings were pleasantly interspersed with songs and pianoforte and violin solos, the instrumental music being contributed by Mr. A. de Pelsenaire and Mr. H. Sawyer.

GLASGOW AND WEST OF SCOTLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

A MEETING of this Association was held on the evening of Tuesday, the 12th instant,—Mr. Hugh Reid, President, occupying the chair.

After the reading of the minutes of last meeting, the following gentlemen were elected ordinary members:—Messrs. J. R. Downie, Mr. Bischoffhousen, G. Chalmers, W. Millar, James Garroway, and James Barr.

The CHAIRMAN proposed that the Association purchase a quantity of trays, measures, a lamp, and other apparatus to be used at meetings where practical demonstrations were given, and the Council were instructed to carry out the proposal.

Mr. T. W. ARMSTRONG then read papers *On Mounting Prints on Glass* and *On Transparency Printing*. For mounting on glass he used starch, first coating the glass and then the damp print, and squeegeeing the two together. He found the use of the squeegee much facilitated by coating the back of the print with starch, which acted as a lubricant and prevented the prints being torn. He had tried gelatine, but found the starch method more simple and quite as satisfactory in result. After Mr. Armstrong had given a successful demonstration of the process,

Mr. J. Y. MCLELLAN suggested that the addition of ox-gall to the starch would make it take more kindly to the polished surface of the glass.

Mr. FALCONER inquired if a mixture of starch and gelatine had been tried.

Mr. JOHN PARKER said he had used the gelatine process for a number of years and was quite satisfied with it, preferring it to the starch process demonstrated by Mr. Armstrong. He found no difficulty in the gelatine setting too rapidly, as during the operation of mounting he kept the glass over a tin tray of boiling water, the steam from which prevented the setting of the gelatine. He thought there was greater transparency in gelatine, and that it was less liable to decay than starch. Further, there was the advantage that, if desired, the gelatine could be rendered insoluble by brushing the back of the print with a solution of chrome alum. He used a weak solution of gelatine, and, instead of applying it with a brush, immersed the print entirely in the solution.

Mr. ARMSTRONG said he had tried a mixture of starch and gelatine, but found no advantage over pure starch. He thought starch was less liable to decay than gelatine, especially in cases where the print might be subjected to damp.

Mr. ARMSTRONG then gave a demonstration of transparency printing by contact and through the camera, using gelatino-chloride and bromide plates.

After a hearty vote of thanks had been accorded to Mr. Armstrong, the meeting adjourned.

LEEDS PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held on Thursday, the 6th instant,—Dr. Thorpe in the chair.

Mr. J. W. REFFITT introduced the subject of *Photographic Enlarging, with a Demonstration of Direct Enlarging on Gelatino-Bromide Paper*. In introducing his subject, Mr. Reffitt said that he thought a short outline of the various enlarging processes would be of interest to the members, especially those who had recently taken up photography. Daguerreotype, or photography on a polished silver surface, was introduced in the year 1839. In the same year Mr. Fox Talbot brought out his invention of making paper negatives, from which any number of positive copies could be obtained. This paper was very sensitive to light. In 1851 Mr. Scott Archer published the collodion process, by which the photographic image was produced on glass, and from this time photographers began to exercise their ingenuity in finding out the best means of enlarging photographs in consequence of the many difficulties and drawbacks in taking large photographs direct. Having photographs on glass by the collodion process, and Fox Talbot's process of preparing very sensitive paper by means of iodide of silver, it needed but little ingenuity to adapt the well-known magic lantern to the production of enlarged photographs. [Mr. Reffitt here illustrated his remarks by going through in form the various processes of taking a small quarter-plate portrait, developing and enlarging the same by means of the lantern to life-size.]. One of the means employed in addition to the lantern was the solar camera or lantern as introduced by Woodward. It was not extensively used in this country on account of the small amount of actual sunshine. Paper enlargements thus produced were very permanent. Mr. Harrison, a well-known Leeds photographer, had exhibited two such enlargements in his window exposed to the direct rays of the sun for twenty-five years, and they showed little if any trace of fading. Enlargements on iodide of silver paper or Talbotype were largely employed for enlarged portraits to be finished in crayon, water-colours, or oil. Messrs. Winter Brothers, Vienna, use a similar process for enlarging on calico, and do a large business, employing the lime light as an illuminant. Another process was to make an enlarged negative from a small albumenised paper print, or from a print by the platinotype process, the latter (specimen exhibited) showing little or no effect of the grain of the small paper photograph. Sometimes it was advisable to make a transparency by contact from the negative, and then to make the enlarged negative to the size required, using some such process as the dry collodion or gelatino-bromide or chloride plates; or by making the transparency on carbon tissue, which, in his opinion, gave transparencies comprising the full scale of tones in the negative. Mr. Reffitt then exhibited a copying camera, and described the various arrangements for enlarging, such as the "horizontal window arrangement," the "vertical skylight, with window underneath," &c., &c. An enlargement could also be made by making an enlarged transparency on glass or paper to size required which could be touched up to improve as much as possible, and then a copy made by contact on dry collodion. The gelatine or carbon method, which was extensively practised amongst those who did a trade in club portraits, was to clean a plate of glass thoroughly, which, after dusting with talc or French chalk, was collodionised, sensitised in the silver bath, exposed with a small negative in the copying camera, and developed to a less degree than a lantern slide; a plain sheet of paper was then coated with gelatine and squeegeeed upon the film. After drying, the picture was stripped from the glass and mounted. Messrs. A. and G. Taylor, of Forest Hill, do a very large business in this class of enlargements—employing twenty-four copying cameras, fitted with twenty-four of Dallmeyer's No. 1 B lenses. Mr. Reffitt mentioned that he had a letter from the late Mr. Dallmeyer in which that gentleman recommended the B series of lenses as the most suitable for enlarging, and he also suggested that four diameters was the extent to which enlargement should be carried. Enlargements on gelatino-bromide paper were easy to make, and its introduction by Messrs. Morgan and Kidd, M. Hutinet, and others would do much to make enlarging popular with amateurs. The paper being very sensitive, enlargements could be easily made at night with a lantern and paraffine lamp. Mr. Reffitt then demonstrated the processes of enlarging on gelatino-bromide paper, using an optical lantern and a four-wick lamp, and, with three minutes' exposure, succeeded in producing a very fine enlargement from a quarter-plate negative, sixe 23 × 18 inches. Mr. Reffitt's paper was fully illustrated by means of diagrams, apparatus, and specimens of enlarging and enlarged negatives by all the processes mentioned.

Messrs. Teasdale, Thorpe, Holmes, and Thornton took part in the discussion that followed.

The following articles we re-exhibited:—A small pocket camera and plate-box combined for thirteen plates, by Mr. Watson; an instantaneous shutter, by Mr. Bradford; an instantaneous shutter, by Mr. Branson; adaptable carrier for unmounted lantern slides, by Mr. Teasdale; gelatino-bromide enlargements, by Mr. Rodwell; and a very fine carbon enlargement, by Mr. Ramsden.

The next meeting, which will be held on Thursday, March 6th, will be an open lantern night. Members wishing to send slides for exhibition must send particulars of their slides, process by which they were taken, &c., to the Secretary, 22, Carr-road, Leeds, not later than March 4th.

BOLTON PHOTOGRAPHIC SOCIETY.

A MEETING of this Society was held at the Baths, on Thursday, the 7th instant,—Mr. E. N. Ashworth in the chair. The minutes of the previous meeting having been read and confirmed,

Mr. MCKELLEN, of Manchester, explained the principles and details of his new camera. There can be no doubt that the inventer has overcome many of the difficulties and inconveniences of the old style of camera, and has secured lightness and compactness without sacrificing rigidity.

Mr. JOHN TAYLOR gave a very instructive explanation of the different modes of enamelling silver prints, and showed the process from the cleaning of the plates to the stripping of the finished prints.

Mr. C. K. DALTON gave the paper on *Platinotype Printing* which he had promised for the previous meeting. He (Mr. Dalton) is a very able manipulator, and his demonstration was one of the best of the season. His method and neatness were very conspicuous, and showed at their best the beauties and simplicity of the process.

Mr. R. Harwood had promised to give a lantern exhibition, but, being unavoidably detained from the meeting, Mr. T. Parkinson very kindly officiated.

The Platinotype Company kindly lent for the purposes of the evening a number of examples of their work, which afforded another enjoyable element in a very successful meeting.

In consequence of the lateness of the hour the further business was postponed, and the proceedings brought to a close by a cordial vote of thanks to all who had assisted in securing one of the best-attended meetings the Society ever had.

Correspondence.

DEFECTIVE GLASS IN DRY PLATES.

To the EDITORS.

GENTLEMEN,—I shall esteem it a favour if you will allow me a small space in your valuable Journal to give vent to a grumble.

The introduction of dry-plate photography has, to a large extent, removed the bulk of the work from the hands of the amateur to that of the professional photographer. The room required and the care and expense necessary for preparing one's own plates have made it impossible for many of us to do the work ourselves. It is a true saying that "if you want a thing done well do it yourself;" and I am sorry to say that it applies to photography as well as to everything else.

I do not wish to find fault with the film of dry plates—that, in many instances, is all that could be desired—but the glass upon which the film is put is horrible. I have tried the plates of nearly all the well known makers, and have found the glass, in many instances, to be exceedingly bad. The plates are not the size stated on the box containing them; they differ in size and thickness, the surface is not smooth, and in many cases they are full of air-bubbles.

I may mention that I only use quarter-plates for my work (photomicrography), so that I cannot speak of other sizes. I have tried nearly all makes with a view of finding the most suitable one for my purpose, and I have finally selected the one which does my work most satisfactorily; but three plates out of every dozen are too large to go into my dark slide, and some of the others are so small that they fall out. Not having all the necessary tools for cutting plates I am obliged to break off the edges until they are the right size, and every time I handle the negatives afterwards I run a serious risk of cutting my hands, besides spoiling half the plates I so deal with.

The gelatino-chloride plates are just the same. I purchased three dozen a few weeks ago, but have only used two dozen as yet, so that my knowledge of them is very small; but out of these I can say with certainty that not one was of the proper size ($3\frac{1}{4} \times 3\frac{1}{4}$); the edges of them were rough, and the surface was anything but smooth—indeed, a few of them would disgrace any firm (I shall be pleased to send you them if you would like to see them).

Plates prepared for lantern slides, if not on good glass of the proper size, are useless. The glass should be as thin as possible, so that when they are mounted they will take up as little room and be as light as possible. I am quite sure that enough profit is made out of dry plates of all sorts to allow of their being manufactured on better glass. Glass is very cheap, and in the end I am sure that it will pay all makers to select the best they can find. The gelatino-chloride plates, especially, should be on good glass, or none will give up the collodion process in favour of them. On comparing some of them with the glass I formerly used with the collodion process I find they are half as thick again; and, not only are they not square, but they are smaller than them. I hope these few words will cause some of the makers to use better glass in their own interests.

I was pleased to see the letter in your last issue from "One Who Would Like to Join," in reference to the forming of a photographic society in Birmingham. I have often wondered that there is not one, seeing the number of photographers there are in the town. Only a short time ago I contemplated writing to the daily papers to propose that one should be formed. I hope this may stir up some of the lovers of the art, and cause them to think the matter over.

Apologising for taking up so much of your valuable space,—I am, yours, &c., JOHN HALL-EDWARDS.

Queen's College, Birmingham,
February 19, 1884.

A NEW EMULSION.

To the EDITORS.

GENTLEMEN,—I send you details of a new emulsion which has never been published:—Take—

No. 1.

Saturated solution of camphor in alcohol	1 ounce.
Bromide of ammonium	60 grains.

No. 2.

Alcohol	1 ounce.
Nitrate silver	90 grains.

Dissolve the silver in a small quantity of distilled water by boiling in a small flask, and when dissolved add the hot alcohol. Add the hot silver a little at a time to the camphor and bromide solution, shaking briskly, and then pour into water in a one-pint glass measure.

Take the precipitated pure bromide and camphor out of the water carefully, place on blotting-paper, laying on a plate on a hot sand or water bath to dissipate the camphor by evaporation. I have had a little experience with it, but I have no time and cannot try it again.—I am, yours, &c.,

February 18, 1884. CAMPHOR.

"AJAX'S" EMULSION FORMULA.

To the EDITORS.

GENTLEMEN,—I enclose you two or three plates showing negatives and transparencies made by myself from the formula I gave some short time since. The transparency is not so clear as I could wish, but with a different developer (the carbonate of soda and pyro. turns brown so soon) I have no doubt they would be as clear as the chloride plates.

The negatives were exposed about two seconds a few days since, so are fairly sensitive. The emulsion was made last September and kept in one part of glycerine, one part of alcohol, and five grains of thymol to each ounce of the mixture.

The plates were developed in—

Carbonate soda	4 ounces.
Common alum	½ ounce.
Bromide of ammonium	¼ ,,
Common water	1 pint.

I have very little time for experimenting, but I am quite convinced that it is only the want of a developer, and any fairly sensitive plates would be absolutely instantaneous. These plates are only trial plates, and one is defective from an air-bubble. I should be glad to see your criticisms in this week's Journal.—I am, yours, &c., AJAX.

[The pictures accompanying the above letter are, technically, among the best we have seen produced by the soda developer. There is an entire absence of the objectionable yellow colour so frequently complained of, while the vigour and gradations are all that can be desired. The want of absolute clearness mentioned may no doubt be remedied by the use of sulphite of soda, or sulphurous acid.—EDS.]

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—ARTISTIC COMPETITION.

To the EDITORS.

GENTLEMEN,—The following have been selected as the subjects for competition during the present year, viz., *Figure:*—The Shepherd, Afflicted, Happiness, Unearthing a Treasure, Indecision, Mother and Child, Wrath, Rustics, Gone, and Age and Youth. *Landscape:*—A Shady Nook, A Country View (including Church with Ivy), A Study of Leaves, Clouds and Trees, A River Scene, Haymaking, The Harvest Field, A Roadside Inn, Summer, and A Village. All pictures to be forwarded to the House of the Society of Arts, John-street, Adelphi, London, W.C., addressed to my care, between the 1st and 4th of December next.

I shall feel obliged if you will kindly insert this in your next issue, as the list published in your impression of the 15th instant contains several inaccuracies. F. A. BRIDGE,
Hon. Sec and Treasurer.

9, *Norfolk-road, Dalston-lane,*
Feb. 16, 1884.

Notes and Queries.

WHICH is the cheapest and most easily-worked lamp for night portraiture for ferrotypes?—NIGHT-LIGHT.

I WOULD like to know if the process for applying photographic printing to pottery is a secret, or if it has been described in the Journal. Also, why cabinet photographs warp after burnishing. The drying of the print after mounting draws or contracts it, but I cannot succeed in getting them flat after burnishing.—PINXIT.

WILL some of your readers kindly say where I could get microphotographs taken of objects which I have? Also where I could get the magnifying-glasses behind which the microphotographs are placed? I refer to those which are put in pencil-cases, pen-holders, and fancy articles. I have tried many large photographers, but cannot get them.—VANNIN.

I SHALL feel much obliged if you can inform me whether varnishing a paper print with plain collodion affects its permanence? And, if so, to what extent? Some time ago an article on copying recommended to varnish with collodion to get rid of the asperities of the paper. I should not like to do this, however, if it caused the photograph to fade, as your article on enamelling would almost make it appear. I hope, however, it is not so, as the process is convenient.—C. P.——We should like to have the experience of others on this question.

WE should be glad of the following information through the Journal:—We are requiring a coating machine for gelatine emulsion plates. We should be glad of any information you can give us, and also the addresses of makers of such machines.—A.O.Z.——In reply: See in our "Answers to Correspondents" column in last week's issue the information on this subject given to "H. Boissonnas." Eastman's machine is now open to the world of photographers—at anyrate to those who reside in this country. The specification, with the drawings, may be procured for a few pence.

A. R. A. writes:—"Being about to devote much of my time to the taking of groups, I should esteem it a favour to receive a few hints as to the best means of photographing them so that the nearest and farthest in the party, arranged so as not to occupy one plane, shall be equally sharp. As for the artistic arrangement of a group, that is a matter which will give me no trouble whatever, as my acquaintance with both the canons and practice of artistic composition far transcend my powers of giving photographic expression to my artistic ideas. Now, I have just posed a small group three tiers deep, and find that when the farthest tier is sharp the nearest one is altogether out of focus, and *vice versâ.* A hint or two in the pages of the Journal, or a reference to any work in which this peculiar difficulty is treated on, will be esteemed by me."——In reply: The difficulties encountered by A. R. A. may be got over *(a)* partially by removing the camera to a greater distance from the group, and employing a lens of longer focus, so as to secure larger dimensions, which would be sacrificed by the withdrawal of the camera. But by adopting the following method *(b)* a perfect preventive of the evil complained of will be secured:—Employ a camera having a swing back, and, after focussing so as to have the most distant figures sharp—these being assumed to be near the centre of the ground glass—then swing the back so as to cause the upper portion to fall away from the lens, and the foreground figures, or nearest tier of figures, will speedily be rendered as sharp as those situated at the greatest distance.

WILL you kindly give me through your *Notes and Queries* the number of the Journal in which the instructions appeared to *make and work the boiling saturated acid solution of sodic sulphite*, as mentioned by Mr. Samuel Fry in last week's Journal.—L. VERNON, Pontypool.——In reply: By turning to page 78 of our ALMANAC for the present year an article on *Successful Development* will be found, in which are given the instructions desired.

ARE there any pantascopic cameras still manufactured? I have looked over the advertising pages of the Almanacs and Journals of the past year without seeing any allusion to it, and I have not been able, either, to find it mentioned as amongst the articles issued by several manufacturers who publish catalogues. There are many beautiful scenes here in Natal which would make charming photographs; but I cannot get sufficient subject introduced by my lens and camera to do even approximate justice to the scenery.—(Rev.) J. B. DICKSON.——In reply: It is now many years since any cameras of the class mentioned have been made. They are occasionally to be met with at second-hand establishments or sale-rooms, but they are not often procurable. An advertisement stating your requirements would prove the best means of having the want supplied.

G. V. says:—"For the past four weeks my negatives have been so intense as to cause considerable difficulty in getting prints during this dull weather. I have steeped one in a strong solution of cyanide of potassium without its becoming evenly reduced; and, acting under the advice of a friend, I have applied a solution of iodine in the cyanide, but only to find the image become dissolved out entirely. Can you inform me of any means of reducing the density without destroying the relative intensities of the several gradations?"——In reply: Let our correspondent make a solution of "ozone bleach" by diluting the commercial article in the proportion of a pint of water to four ounces of the bleach, and immerse in this his over-dense negatives. He will find that they will become reduced with a degree of evenness altogether impossible to obtain with cyanide, either alone or with iodine.

Exchange Column.

I will exchange a tripod and lens for a background.—Address, THOMAS RAYMENT, Queen's-road, Egham, Surrey.

Wanted, microscope or scientific apparatus. Cash or offers for Lancaster's half-plate lens, stand, and home-made camera, double back.—Address, C. L. CHAMBERS, 8, Gordon road, West-hill, Hastings.

What offers in ferrotype plates, mounts, silver, collodion, or other photographic material, for a camera and lens taking four Victorias or midgets on a quarter-plate?—Address, PHOTO., 1, Cotton-buildings, Exeter.

I will exchange an excellent *carte* lens, in perfect condition, by a good maker, for an enlarging lantern and lens, which must be good and in working order.—Address, G. ARTHUR, care of Mr. W. H. Fenton, Mount Pleasant, Mirfield, Yorks.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

IN OUR NEXT. Stannotype No. IV.

EXCHANGES.—David M. Linley; Horace Rutley; S.; Sulphite. In our next.

D. N. HUTCHINGS (Iowa).—See answer to "A. O. T.," under the heading *Notes and Queries.*

THOS. DEAN.—Plain papers, of almost any tint, may be procured at any paper-hanging manufactory. They are sold, we believe, under the designation of "grounds."

J. A. (Leeds).—Decidedly you have added too much acid, and that is, doubtless, the cause of the films splitting off in the bath. Neutralise it with a little of oxide of silver.

J. G. ROBB.—As a substratum in the collodion process nothing is better than dilute albumen. The white of one egg in thirty or forty ounces of water is a good proportion to use.

A. B. C. (Yorks).—If you carefully read the articles which have already appeared on the stannotype process you will have no occasion to put such questions. They are already answered.

G. A. TOOMEY.—Make a varnish by dissolving gum and arnica in benzole; you can have nothing better to dry without heat. This is what used to be employed for the old glass positives, and is probably what you are inquiring about.

S. A. G. J.—The pictures are very fair, and we think you might probably obtain an appointment as assistant operator. It is quite possible, however, that you may experience some little difficulty in obtaining the salary mentioned.

G. R. CARD.—You will find it convenient in working in a studio such as shown in your sketch to have a double set of curtains, so as to work each way, particularly if the sun fall on the light A B during business hours. That form of studio requires more skill, to work it successfully, than one of the ridge-roof or "lean-to" form.

J. R.—1. Neither of the gelatines you employ have a tendency to give a matt surface.—2. You ought not to get the greenish tint with the developer you employ. The ferrous oxalate developer yields more of a wet-plate character than the pyrogallic acid.—3. Opinions are divided as to which kind of surface gives the best results.

A. WILLING.—No wonder the gloss is not preserved if you mount the pictures in the way you state. The mount must be attached to the print while it is still on the glass and before it has become dry. You had better follow the instructions you have received, notwithstanding that they may entail somewhat more trouble than is agreeable.

S. S. G.—A formula for the old toning and fixing bath is given in a leading article in the present number.

AMATEUR, who writes on a post-card, has not conformed to our rule by sending his name and address; hence his query remains unanswered.

MEXICO.—The best lens for your purpose will be one of the "universal" or "group series." Next to one of these will be a lens of the "rapid" type. It will be better, in practice, to select one of such a focus that it will cover a plate a size or two larger than you require, as then it can be employed with the full opening, which you will find advantageous.

WARDEN.—The lens, as you infer, may be an inferior one; but you must bear in mind that it is impossible to make large portrait lenses of five or six inches in diameter and of short focus with the same degree of perfection as smaller ones. If you expect the same qualities in a large instrument as you get in a *carte* lens you will certainly meet with disappointment. Keep this fact before you when criticising large portrait lenses.

A DEVONIAN.—1. The lime in the water will, practically, do no harm to the pictures.—2. Ruby glass is not necessary for the window of the room in which you are going to sensitise the paper; one thickness of orange is quite sufficient.—3. Messrs. Marion and Co.—4. The "universal" will be better than the "rapid symmetrical" for your purpose.—5. Better have the light from the north; it is easier to manage.

RECEIVED.—K. Ogawa (Boston, U.S.); R. S. Redfield (Photographic Society of Philadelphia); W. H. Wane (Franklin Institute); C. F. Richardson (Leominster, Mass., U.S.A.). Thanks.

IN TYPE.—Communications from Col. Stuart Wortley, J. Nicol, Ph.D., J. Harmer, W. H. Harrison, and "Free Lance." We hope to include these in our next issue.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 27th inst., the subject for discussion will be—*On the Preparation of Lantern Slides.* As this will be a lantern evening, members and visitors are invited to bring slides.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The next monthly technical meeting of this Society will take place on Tuesday next, the 26th instant, at 8 p.m., at the Gallery, 5A, Pall Mall East, when the evening will be devoted to an examination of transparencies, &c., by the Society's oil lantern.

ROYAL INSTITUTION OF GREAT BRITAIN.—The following is the syllabus of a course of six lectures on *Photographic Action Considered as the Work of Radiation*, to be delivered by Captain Abney, R.E., F.R.S., on the following days, at three o'clock:—Lecture I.—Saturday, March 1st. *Molecules and Atoms—Effect of Radiation on Matter—Examples of the Chemical Effect of Radiation.* Lecture II.—Saturday, March 8. *Rapidity of the Effect of Radiation—Physical Development of the Molecular Changes.* Lectures III. and IV.—Saturday, March 15th and 22nd. *Absorption of the Energy of Radiation, and the work performed by it—Analysis of Photographic Action by Means of the Spectroscope—The Visible and Invisible Regions of the Spectrum.* Lecture V.—Saturday, March 29th. *The Behaviour of Photographic Compounds in the Spectrum, and the Conclusions to be Derived from the Results.* Lecture VI.—Saturday, April 5th. *The Comparison of Thermal Effects with the Chemical Effects Produced by Radiation.*

SUICIDE BY CYANIDE OF POTASSIUM.—Dr. Wynn Westcott held an inquest on Monday last, the 18th instant, at the Hampstead Workhouse, into the death of Alfred Pierpont Chambers, 59, an artist, who had lived at 211, Clapham-road.—The evidence of his brother-in-law and of Elizabeth Patterson, servant to the deceased gentleman, was to the effect that since the death of his wife, in November, 1882, he had been very strange in his manner. On Wednesday evening he left home shortly before eight o'clock, and never returned.—William Fletcher, gravedigger at the Hampstead Cemetery, stated that on Thursday morning, as he was going from one part of the cemetery to another, he saw a man lying face downwards on the grave of Mrs. Chambers. He found life extinct, and he at once called assistance, and the body was then removed to the police station.—Dr. Gresvenor said the gentleman had evidently been dead ten or twelve hours when he saw him. He had made a *post-mortem* examination, and found that death was due to poison taken in the form of cyanide of potassium, which must have been swallowed a few minutes before death.—The jury returned a verdict of suicide while of unsound mind.

LONDON GAZETTE, *Tuesday, February* 19, 1884.

RECEIVING ORDER AND DATE OF PUBLIC EXAMINATION.

DUNCAN JOSEPH GRANT, 53, Llewellyn-street, Pentre Ystradyfodwg, near Pontypridd, artist, picture-frame maker, and photographer. Pontypridd Court, March 14th, at noon.—First meeting February 29th, at three p.m., at the Official Receiver's Office, Merthyr Tydfil.

CONTENTS.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1243. Vol. XXXI.—FEBRUARY 29, 1884.

THE PERMANENCE OF PHOTOGRAPHS MOUNTED IN OPTICAL CONTACT WITH GLASS.

Whatever may be said with reference to the artistic merit of photographs either enamelled or mounted in optical contact with glass, one thing is certain, namely, that such pictures do undoubtedly meet with considerable favour on the part of the general public. Therefore, so long as the public taste runs in this particular direction so long will such pictures continue to be supplied. At the last meeting of the Glasgow and West of Scotland Amateur Photographic Association the subject of mounting prints in optical contact with glass appears to have been one of the topics discussed. Some of the members advocated the employment of starch and some gelatine, while others suggested a mixture of the two. The object of the present article is to direct particular attention to the fact that it is of primary importance the mountant, whatever it is, should be one which will have no deleterious action on the picture—a matter too often overlooked.

Our attention has been called of late to the large number of faded photographs, mounted on glass, which are to be seen in the shop windows of many fancy stationers in the metropolis. This has caused us to observe them more closely than we perhaps otherwise should have done, with the result that, in almost every instance, when a picture of this class has faded it has been one of those "scraps" of which such large numbers are produced—many of them on the continent, and at an exceedingly cheap rate. It is the public exhibition of such considerable numbers of faded and fading specimens of these pictures in the shop windows which has, doubtless, given rise to the idea that prints mounted in contact with glass fade more rapidly than those on cardboard. Now, if anything can conduce to the permanence of the photographic image, one would think it should be the hermetically sealing it between two impervious surfaces, as then it must be perfectly protected from all atmospheric influences. But experience teaches us that there are instances where such is not the case; in fact, this treatment, on the contrary, sometimes appears to hasten decay rather than prevent it.

Only a few weeks back a fancy stationer (who keeps a somewhat large stock of these "scrap subjects," mounted on glass, with the usual black margin and gilt metal rim) showed us a considerable number which had faded badly; indeed, they were quite unsaleable, although they had only been in his possession for a few months. He remarked at the time that he had received many complaints of fading from customers to whom he had supplied them. On inquiry we found that the pictures in question were supplied wholesale at such a very low price that it could not reasonably be expected that any great care had been bestowed on their production.

In our last volume (page 199) we devoted an article to the consideration of the question whether prints "enamelled" with gelatine were likely to prove more or less permanent than corresponding prints not so treated. We then pointed out that, under certain conditions, the enamelling would prove no protection against, but, on the contrary, might possibly conduce to, fading. What was then said in reference to enamelled prints applies equally well to prints mounted in contact with a glass plate.

It is clear that if a print have been but imperfectly fixed and washed, and, consequently, contains within itself the elements of destruction, rendering it impervious to the atmosphere will afford it little or no protection. If, at the same time, the material with which it is rendered impervious contain acid or oxidising properties, it is easy to conceive that the fading may be considerably hastened by the treatment. Again: even if the print have received every care in the fixing and washing, and it be afterwards impregnated with an acid sample of gelatine, no additional permanence can reasonably be expected to result therefrom; on the contrary, it must act injuriously rather than otherwise.

Now, after what has been said, it is not difficult to surmise the reason why so many of those cheap productions to which allusion has been made fade so rapidly. They, doubtless, received but little attention in the fixing and washing operations, and were afterwards mounted with an acid sample of gelatine. Nearly all foreign gelatines, it may be mentioned, are acid, and these are the kinds most generally used for enamelling or mounting on glass, by reason of their freedom from colour and their transparency. The more colourless and transparent the sample the more acid it will generally be found; therefore, in no case should a gelatine be employed—either for enamelling silver prints or mounting them on glass—without previously neutralising the free acid. But it will be far better to avoid using such gelatines altogether for the purpose, and employ only those which are neutral in the first instance, like those of Messrs. Nelson, Dale and Co., or of most other English manufacturers. They may not be quite so colourless or transparent as foreign gelatines; but in the extremely thin films which are here employed no difference between the two can be distinguished in the finished picture.

What was said a fortnight since, when giving our experience of the increased permanence conferred by enamelling, applies equally well to photographs cemented in optical contact with glass. In our hands they have always proved more permanent than ordinary prints. But the prints upon which we have based our experience have been in each case both carefully fixed and washed before being mounted on the glass or enamelled, and the mounting or enamelling has always been effected with the finest kinds of English gelatine, for the reason already mentioned.

It has been suggested that a small proportion of chrome alum should be added to the solution of gelatine used for mounting the prints on the glass with a view to rendering it insoluble, and, therefore, less absorbent of moisture; but we prefer to employ the plain gelatine. If, however, it be desired to render the paper itself impervious, it is better to coat the back of it with collodion containing castor oil; but we consider this quite unnecessary.

PIRATING LANTERN SLIDES.

Bearing in mind what we said a few weeks since, with regard to the duplicating of negatives under circumstances in connection with which a high degree of success was achieved, it will readily be understood that the same law of reproduction applies to transparencies, and a correct inference will be deduced from this that manufacturers of transparencies are, beyond all other photographers, liable to have their works pirated.

But the low prices at which the genuine productions of such manufacturers can be readily procured in this country, together with the possible fact that any one, or all, of them may be copyright, have hitherto acted as deterring agents in their fraudulent multiplication. These influences are, however, only operative in Great Britain and Ireland. In countries where there is a large or even moderately-large demand for such productions, where the prices are four times in excess of ours, and where there is no legal restraint upon the copying of English slides, it is scarcely to be wondered at if the temptation to become pirates is too great to be successfully withstood. In a letter having a bearing on this subject, from Mr. J. T. Taylor, in our issue of the 15th instant, he dimly hints at the possibility of the copying, by American dealers in and manufacturers of lantern slides and appliances, of York's slides, and presumably others which are of English manufacture. But another correspondent, whose communication will be found on page 143 of this number, is less reticent; for he says that when residing in the United States he, as a photographic operator, was often called upon to copy English productions for commercial purposes. It was quite well understood by him that such copies were to be sold as "imported" productions at the prices charged for plain imported slides, namely, five shillings and twopence each. So long as there is no international copyright law—to which we may also add that so long as there is such a high protective import duty on photographic transparencies—just so long will English makers have to submit to the risk of having their works copied.

An extensive manufacturer of lantern slides, who procured the services of skilled draftsmen to make delicate outline sketches which were afterwards photographed and coloured, once told us that he could immediately detect any piratical reproduction of his designs. Having obtained his permission to make an attempt we, in the course of a fortnight, handed him a nicely-executed painted lantern slide, showing a view of the rocky temples in Petra. He observed—"That is the same slide you purchased the week before last." "No," we replied, "it is only a copy of it." Applying a magnifier, he said "It is genuine," and pointed out certain marks which were considered as tests; but by showing him the original and the copy side by side we soon convinced him that inexorable photography made short work of his private test marks. But reproduction or duplicating of lantern slides does not necessarily mean piracy, although the one is so frequently a concomitant of the other. If an exact reproduction be required no better or simpler means can be adopted for doing so than by superposition; but this is only suitable when the dry process is to be employed throughout.

It will be found preferable, especially if a number of copies are required, to make an enlarged negative from the transparency, the degree of amplification being about two diameters. When this negative is finished it may, in some cases, be found advisable to subject it to the operation of a skilful retoucher, because many landscape subjects have the foliage much heavier than is thought desirable, and this, together with similar defects, may be easily remedied by stopping out and imparting to the lights and shades the requisite degree of harmony. The negative, when thus improved, is made use of for printing transparencies by wet collodion and the camera, the degree of reduction and amount of subject included being now entirely under control, which could not possibly be the case were the other method adopted.

We have spoken so frequently of the manipulations to be employed when making transparencies by wet collodion that we do not feel it necessary to recapitulate them here. It may, however, be needful to say that a transparency produced from another by the system described is not necessarily inferior in any respect to the original from which it was obtained, but it *may* be much superior in every quality except sharpness. We have had a three-inch transparency, produced in the manner described, projected on a thirty-foot screen with a marked advantage over the original when projected under similar circumstances.

COLLECTING RESIDUES.

Mr. F. W. Hart's lecture, given in full in our last issue, will serve as an excellent reminder of the large amount of the precious metals employed by the photographer which can, with due care and the aid of suitable appliances, be collected from the so-called "waste solutions." The time is gone by when it was necessary to be continually insisting upon the desirability of this collection—when few photographers took any care even of the washings from the prints before toning; yet, strange to say, proof is continually reaching us that the saving of hypo. solutions is still, comparatively speaking, an unusual occurrence. It would be difficult to say why this should be so, were it not that the care of residues too often falls into the hands of assistants who have had no experience in treating such residues, and whose chemical attainments are at too low an ebb to enable them to initiate any such process themselves.

Mr. Hart did well in bringing before his hearers a great variety of important facts, as well as a very complete system of treating all waste likely to accumulate on a photographer's premises, and his communication was full of practical working details. It was, however, treated in a manner calculated to be far more valuable to the photographer in a large way of business than to the artist in a smaller way or to the amateur, and a little annotation of his remarks will help to show the latter that the preparations for dealing with valuable solutions are by no means such a complicated matter as the tyro, upon reading the lecture, might imagine. For such, of course, it was not intended.

In the first place, the question which may most particularly be considered is—whether to reduce the accumulation of residues at home or sent to the refiner's. Mr. F. York stated that his own experience led him to believe that between the two methods there was little to choose. He had tried both, and obtained about the same money value from each. When the attempt to make the reduction is undertaken by the photographer himself he should most carefully keep in mind Mr. York's dictum—that "the danger of not effectually and thoroughly performing the reduction was one which those who were not engaged in it as a business should carefully guard against, or they would lose rather than gain by their trouble." He narrated an experience of his own where he found that the flux left after the reduction contained silver to the extent of ten shillings' worth per pound—a waste or loss far in excess of what the refiner would charge for performing the reduction himself, after taking all risk, and allowing the full value of the metal contained.

When the quantity is at all large the refiner's charge is not likely to exceed five per cent. of the total value of the metal present, and perhaps decidedly less. Out of this has to be paid labour, fuel, crucibles, wear and tear of furnace, &c. When the photographer employs a refiner of standing to reduce his work we very much question whether he is not a gainer, and does not get more value than he who spends a good portion of a day in treating a batch of his own residues.

There are, however, many photographers who like to perform operations of this kind on their own premises for the mere interest taken in the work, and without regard to the relative economy of the two modes of dealing with the material. To them we would say that they can work upon fairly large quantities of residues without going to any expense in furnace building, or even purchasing a gas furnace, which is more practical with small than with large quantities. With careful treatment it is quite an easy matter to reduce (say) half-a-pound of chloride on an ordinary blacksmith's forge, the formula for mixing the flux for which has been given in our pages; or one of those given in the paper we are discussing may be chosen, they being little different.

One fact must be borne in mind: it is that the carbonate of soda mentioned in most formulæ is not the white powder often called the "sesquicarbonate," but that represented by the common washing soda or by soda ash, the latter not now being a salt commonly met with. Further: there will be no loss if the precipitate of chloride be collected and dried without spending time upon any preliminary washing.

The experience of a practical man like Mr. York, who is accustomed to deal with large quantities, should outweigh any theoretical considerations; but we feel bound to say we do not understand the result he obtains, namely, a troy ounce of silver from three avoirdupois ounces of chloride, and one-fourth of the weight in metallic silver from sulphides. In our experiments we have obtained—what theory would indicate—far larger proportions, and sulphide certainly should be richer than chloride. This proportion, however, could be readily accounted for by the supposition that the printing hands are not careful in keeping the precipitates free from foreign matter.

The idea of using a paraffine oil cask is a decidedly good one, where space is no object; but as there should always be two receptacles for each kind of residue (chloride and sulphide), four such casks would occupy no small space. We would also place the taps nearer the bottom than was mentioned at the meeting to which we have referred. Six or eight inches would be quite sufficient, and would entail less frequent drawing off of the liquid. These casks are readily cleaned with boiling water, as they are coated inside with a thin film of glue to aid in rendering them oil-tight.

The stoneware vessels with conical side are very good, as also are the wooden vessels made in a similar form, as described many years ago by one of our contributors. Hydrochloric acid—or "spirits of salt," as the crude acid is commonly designated—is far preferable to salt for precipitating the chloride. It is then certain that the whole of the precipitant is in solution instead of, as is often the case, at the bottom of the cask, a lump of salt being usually thrown in, and perhaps one stir given to the water without the salt ever reaching the top. When both first and second washings from the prints are preserved the precipitate in a large vessel will take far longer to subside than the two hours Mr. Hart named. Perhaps as good a method as any of adding the acid is to throw a certain quantity into the bottom of the jar or cask each time the supernatant fluid has been drawn off. It will then need no great amount of stirring when the vessel is full to ensure thorough admixture of the precipitant. One point in this connection should not be forgotten: many photographers now use ready-sensitised paper made by blotting off and treating with citric acid. The photographer here must not expect much value from his washing waters when such paper is used.

With regard to hypo. precipitates: we again call attention to the great value of precious metal that spent hypo. solution contains, and point out, as has been done for many years past in these pages, that it can be obtained quite as readily as chlorides from print washings, and with very little annoyance. It is only the experienced manipulator who can throw down sulphides so as to cause no disagreeable odours in the room; but, if care be taken not to add too much at once, the smell will be reduced to a minimum and will quickly pass away. When too much sulphide has been added a scum very quickly forms upon the surface of the solution, and a workman of average intelligence would quickly learn, by observing this point alone, how to apportion the quantity of sulphide to add. When this scum is present there will always be a foul smell from the solution, and especially so when drawing it off.

Another source of failure to those who are trying this plan for the first time is the liability of the sulphide to become spoiled by keeping. It is always covered with a useless crust, and this crust gradually deepens by exposure to air till the whole piece is useless for the purpose. When broken into pieces its quality can be ascertained, the unaltered material being of a rich, glassy, liver colour, while the useless part is a dull, opaque greenish- or yellowish-grey. We are inclined to think that this proneness to change in the sulphide may account for a great deal of the indifference to hypo. residues which, there can be no manner of doubt, widely prevails.

We trust that our hints may lead to a greater economy in photographic processes, which, in these days of competition, is a matter of far greater importance than ever it was; and in conclusion we may say that we give it as our well-matured opinion that in the long run it will, in most cases, pay the photographer better to send to the refiner the precipitates his care has brought together, rather than risk wasting and losing a considerable proportion by indulging in unpractised reducing experiments.

In speaking of the comparative permanence of negatives intensified with mercury, Dr. Nicol is not alone in ignoring the difference between collodion and gelatine negatives. We have over and over again expressed the opinion that, by giving a proper amount of washing after each operation in the process, mercurial intensification—in some of its forms, at least—is as much to be trusted as any other. But how is one, now-a-days, to define what constitutes a sufficient washing? What will suffice with some gelatine films may prove wholly inadequate with others, and hence the uncertainty. With collodion films, however, the salts are readily enough removed, and, consequently, collodion negatives intensified with mercury have proved more lasting than gelatine ones. This fact may prove that "the fault lies in the method and not in the material;" but it does not remove the uncertainty which attaches to mercurially-intensified gelatine negatives.

The Northampton Photographic Society—or, rather, the photographic section of the Museum—have decided to hold an international exhibition next December, preliminary details of which are given in our advertising columns. With the liberal prize list announced, and the assistance of so able an Hon. Secretary as Mr. Harry Manfield, there is little fear as to its ultimate success. We shall have more particulars to give in a future number.

As will be seen by an announcement in another column the Postal Photographic Society is about to lose the services of its indefatigable Honorary Secretary, Mr. H. H. Cunningham, to whose energy and perseverance so much of the success of the Society is due. While regretting Mr. Cunningham's departure from the scene of his photographic labours, we cannot but congratulate him on his appointment to the important position he is about to occupy, and we hope he may long be spared to dispense justice to the colonials, and, when time permits, to send us some account of his photographic experiences in a hot climate.

The microscopists have seized and adopted many photographic processes, not the least interesting adaptation being emulsion preparations, even down to "pellicle." The only difference is that the emulsions are used by the microscopist for injecting prepared tissues and not for development, though some of the emulsions so used are prepared by development. Thus, a mixture is made of five ounces of gelatine, three ounces of common salt, and a pint of water; and also a solution of nitrate of silver, three ounces in half-a-pint, the former being slowly poured into the latter whilst stirring. After cooling and squeezing through a net into vermicelli-like threads this mixture is added, in daylight, to a mixture of a pint and a-half of saturated solution of oxalate of potassium and half-a-pint of saturated solution of sulphate of iron. This is for a black emulsion. It will thus be seen that the working photographer would be the most likely person to be found who could compound the mixture with advantage.

It may be noted, further, that the emulsions are made into dried pellicles by warming till fluid and then pouring on to sheets of parchment (*query:* parchment paper?) saturated with paraffine, from which it can easily be separated, dried, and cut into slips.

The question of stoves, fire-places, or hot-water pipes is one of perennial interest and to the photographer as much as anyone, and we note a very interesting fact in connection with the subject which recently was incidentally alluded to at a meeting of the Physical Society when a topic of high abstruse interest was under discussion. When a current of air is produced by the impinging of cold air upon heated surfaces a peculiar motion of the molecules is brought about, and, as a consequence, Professor Forbes stated that Aitken shows that a room heated by a stove will have dustier walls than one heated by a fire, owing to the air being hotter than the walls. Emulsion workers may take a note of this fact.

The interest excited by Mr. W. Crookes's radiometer will not readily be forgotten by photographers. They may also remember that the instrument was quickly copied on the continent, and "light-mills" made there and sold in this country in large quantities. It appears that several philosophers have been working in a parallel line with Mr. Crookes's investigation, and engaged in devising a sound-mill—that is, a mill moved by the agency of sound instead of light. They have been successful, and a variety of forms of the instrument is illustrated in a recent number of *Nature.*

On the 19th of March next the Council of the Meteorological Society have arranged to hold an exhibition of thermometers, and the committee will be glad to show any new meteorological apparatus invented or first constructed since March last, as well as photographs and drawings possessing meteorological interest.

There should be no lack of photographs; for, as our columns have testified, many very interesting representations of meteorological phenomena have lately been taken. Few such pictures could be more interesting than that of the lightning flashes lately alluded to by us, and which, *en passant,* we may say are almost equalled in interest by a series of photographs of the electric spark, taken instantaneously. They are reproduced in our contemporary *La Nature,* printed by a process of heliogravure.

Then, again, in the same journal there is an illustration, also from a photograph (taken by M. Ch. Mossette) of a display of the strange after-glow, or "crepuscular light," as that periodical terms the display in language far more precise than the accustomed "remarkable sunsets" of the English papers. The picture is a valuable contribution to the records of the phenomena, and represents an appearance which we do not remember having seen described in any of the accounts of the phenomena yet published. There is a distinct view of the open country with a very low horizon, the camera having been fixed so as to obtain as much sky as possible. Immediately over the horizon line lie a few clouds, while the whole space overhead is marked out by a huge parallelogram (grey upon a darker ground) crossed with light streamers, while at one end of the figure a further series of upright lines about equal in width to the lines of the figure is seen, and give the impression of a number of the forms lying one behind another. The whole effect is most striking, and the photographer is to be congratulated upon his successful rendering of a phenomena most interesting to everybody at the present time.

The great explosion at Victoria Station was only prevented from becoming a dire catastrophe by the difference of a few minutes of time. As it is, not a life was lost and scarcely any injury sustained by the explosion itself. A very wise step has been taken in securing photographs of the scene of the disaster. Nothing was allowed to be touched or removed till half-a-dozen photographs had been secured. The aid of photography has been utilised times innumerable in recording the results, and even the very act, of dynamite and other explosions; but no photographs—not even those of the heaving mountains of water thrown high up by the firing of submarine mines photographed by the authorities at Woolwich—suggest anything so appalling as the possible results that might have followed the dastardly act that is now creating such excitement in the metropolis.

It is not every amateur photographer who receives a gold medal from the Royal Astronomical Society, yet we are sure our readers will be ready to join in congratulating Mr. A. A. Common upon the honour recently bestowed upon him. It will also be encouraging to all patient, careful workers to learn that the President stated the Council has been less influenced in awarding medals by "originality in the methods adopted, than by the great practical success which has attended Mr. Common's efforts in a most important and interesting field of astronomical research."

Mr. Common was engaged in astronomical photography so far back as ten years ago, his experiments being made with a five and a-half-inch reflector. He then, after abandoning the idea of making a reflector himself, although he had purchased the discs of glass for the purpose, obtained an eighteen-inch reflector by Carver, which he had mounted under his personal supervision from his own designs. This he was able to work with in 1877. Next he had a far more powerful instrument, and in 1879 he started work with a thirty-six-inch mirror. This instrument, though in use for other work, has been mainly devoted to photography. Mr. Common's first attempt at the object now so inseparably connected with his name—the nebula of Orion—was on January 20, 1880, and resulted in failure. With the aid of gelatine plates, and by continual improvements of the driving-clock, he was able to obtain what was perhaps the earliest successful photograph of a comet, on January 24, 1881. A photograph of the nebula was, at last, obtained on March 7, 1882, and received great praise. Further improvements were made, and on January 30, last year, the celebrated photograph exhibited at Pall Mall was secured. Mr. Common has still continued his experiments in many directions, and he has found that the ability to give so much as ninety minutes' exposure—which the perfection to which he has brought his instrument allows him to do—enables him to produce many results unattainable by other means.

It is not given to every great poet to reach straight to the heart of men as did Longfellow in so many of his poems. Among every English-speaking community in the world the lines he wrote are as "household words," and when he went from among us he left a void difficult to fill. His songs remain, and will remain. In years to come many a sad soul held by a worn, tired frame will be cheered by them; and his words "Let us then be up and doing, with a heart for every fate," will at once encourage and offer hope. It will be gratifying to photographers to learn that their art has been instrumental in enabling England to pay her tribute of respect to his memory. Every one will be familiar with the grand head of the poet which has been so artistically treated by the photographer—notably one picture (by Sarony, we believe), taken about twenty years ago, which was almost the finest photograph ever produced up to that time. These pictures have now been sufficient, placed in the hands of a clever sculptor, to enable him to obtain an excellent likeness in marble. A three-quarter length figure, produced with no other aid in securing the likeness than photography, has been executed by Mr. Brock, and will be placed in Poet's Corner, Westminster Abbey, tomorrow.

THE LIVERPOOL ASTRONOMICAL SOCIETY AND STELLAR PHOTOGRAPHY.

We are glad to see that the question of stellar photography is being taken up by the Liverpool Astronomical Society. We have already noticed in these pages some of the results already obtained. The last one we recorded was the photographing of the comet Pons-Brooks by the Rev. T. E. Espin. At the meeting of the Society, on Monday evening, February 18th, Mr. Isaac Roberts, F.R.A.S., one of the vice-presidents, gave some results he had obtained with a variety of lenses. In all he had taken twenty-seven photographs. The cameras had been attached to the declination axis of his telescope, which is an equatorial, and driven by clockwork. The object in view was to determine what were the best plates to use and what the best size of lens.

Theoretically, the larger the lens the more stars ought to appear on the plate, or where the lenses were of different apertures the large lens ought to photograph the same number of stars in an exposure which would be less in accordance with the differences between the apertures. To test the various lenses it was necessary to have equal conditions. The plates were taken from the same packet; the lenses were all mounted in cameras on the same equatorial stand; the same group of stars were photographed, and the same exposure used for all. Under these circumstances the conditions were precisely similar, and the differences obtained would be due to the lenses only.

The exposures given were, as a rule, under half-an-hour; for the experiment was not to photograph as many stars as possible, but only to determine the space-penetrating power of the lenses. Hence the length of the exposure was generally short, sometimes being only a quarter of an hour. The objects selected for trial were the Pleiades and the region of the great nebula in Orion. In both, stars ranging from sixth magnitude to tenth magnitude are properly clustered, while the stars below the tenth magnitude are innumerable. The nebula in Orion itself, too, offered an excellent test for the penetrating power of the lenses. The apertures of the lenses tested were three-eighths of an inch, one and a-half inch, two inches, three inches, and four inches. The images given by the three-eighths of an inch were so small as to be with difficulty distinguished from specks on the plate. The one and a-half inch lens drew the stars out into triangles, showing that, although for landscape work the lens seemed perfect, yet when subjected to this test it was not perfectly figured. Various stellar photographs were taken with the one and a-half inch, and always with the same result.

Of all the lenses the two-inch seemed to work best, and several enlargements were shown at the meeting from the negatives taken with this lens. The increase of aperture, for some reason that Mr. Roberts could not explain, did not seem to give a proportional increase in the number of stars. The four-inch lens, for instance, with the same exposure did not show many more stars, but those it did show seemed blacker and sharper. There can be no doubt, we think, that the inaccuracies of lenses may be detected by taking stellar photographs with them. The brighter stars can be photographed in a very few minutes, and the plates could be made especially rapid for this purpose.

As regards the plates used, Mr. Roberts declined at present to say which were the best for stellar photography. Evidently however, much might be done in the laboratory—more, even, than with the increasing aperture of lens; for the plates could be made more sensitive, and thus greater results be obtained.

One point of great value was brought to light in the course of the discussion which followed Mr. Roberts's paper:—With whatever aperture a group of stars may be photographed the relative impressions on the plate remain constant. If three stars are photographed with different apertures the magnitudes as shown on the photographs are the same in all. This point is a very important one; for it shows that the differences are really due to the chemical light in the stars and not to any peculiarities in the lenses. In the Pleiades both Mr. Espin and Mr. Roberts find independently that some of the brighter stars are absent from the plate, while many stars of less magnitude to the eye have left their impression on the plate.

We are pleased to hear that the Liverpool Astronomical Society is taking vigorous measures to continue the work of stellar photography. A very powerful instrument will soon be in position, and then, we believe, a systematic survey of some part of the heavens will be undertaken, and doubtless the results will be valuable and interesting. In the meantime we shall await with interest any further researches into the powers of lenses and the most suitable plates.

DARK ROOM ILLUMINATION.

In an article in your last issue Mr. Herbert S. Starnes quotes an experiment of Mr. A. Cowan's, but has unaccountably omitted to mention a most important factor in this experiment, and the omission renders entirely misleading the argument which Mr. Starnes bases upon Mr. Cowan's statement.

Mr. Starnes states that Mr. Cowan "found that by transmitted light he could obtain a deposit in five seconds; but with a reflected light, with more apparent light to the eye, he could not obtain a deposit in 180 times that period of time." He has ommitted to say that the lights employed were totally different. The light giving the deposit in five seconds was Mr. Cowan's former dark-room lantern fitted with the usual red mediums, while that which gave him a better light, with no deposit, in the longer period of time was the combination of yellow paper and green glass. Mr. Cowan mentioned that simultaneously with changing the colour of his light he had arranged to let reflected light only fall upon the glass, and gave as his reason for so doing that the window could then be equally illuminated all over instead of having one special bright spot opposite the gas jet which formed the source of light.

That there is some advantage in using reflected light is what might be expected from the fact that such a good judge and scientific investigator as Mr. Leon Warnerke mentioned long since that he used it in his coating room. The lantern which he described some year or more ago, at one of the meetings of the London and Provincial Photographic Association, consisted of a hemispherical reflector painted red, with its opening covered by ruby glass. The lamp which it contained was furnished with a screen, which prevented any rays from the flame direct passing through the glass. Substituting yellow for red as the reflector, green glass and yellow paper for the ruby glass, and used as a front instead of a ceiling light—such was the manner in which Mr. Cowan obtained his successful results. That reflected light, however, should give a light fifty times stronger to work by than a light of the same safety for the plate obtained by transmission is a mere unproved guess of Mr. Starnes, and he would do well to bring some evidence, based upon experiments which can be repeated by others, to substantiate it.

The box-lantern which Mr. Starnes showed at a meeting of the London and Provincial Photographic Association is certainly convenient for travelling and very easily made. When it is, instead of the brown colour first shown, painted of bright, deep yellow, and fitted with a green glass in front, as it afterwards appeared, it is doubtless very effective.

Since the appearance in The British Journal of Photography of January 25th of my article on *Dark Room Illumination* I have supplied many small patterns of glass and paper, and from the letters I have received I am happy to say that already many photographers have found relief in abandoning the old red light. There has been a difficulty, however, in some places in procuring glass of the right tint. Perhaps with increased demand this difficulty will disappear. I observe that many speak of the glass I use as "cathedral green." I have never used the expression myself. "Cathedral" is a certain make of glass that is not quite clear and even, and is of all colours. It happened that I could not obtain the glass of the colour I wanted, except of this particular make; but it may be that some makers have a suitable colour—a light yellowish-green, not at all bluish—in ordinary pot or stained sheet.

Since writing the above paragraph I have seen a glass which I have not yet tried, but which appears to be very suitable. It is known as "muffled No. 6A," and is intermediate in depth between the two shades of cathedral glass which I have referred to. I should say that one thickness of this glass, with sufficient thicknesses of paper, would answer for any light. The paper is known as "No. 5½ deep yellow demy." Whether these numbers refer to similar colours in the case of articles kept by dealers who are not supplied from the same factories I am not at present able to say.

I find, too, that I have not in all cases been understood as to the quantity of glass and paper used. I stated that I used for daylight a fixed screen of one thickness and two of paper, and that in front of this was a movable screen similar, which I draw aside as soon as the development is complete, or in a very dull light. This, of course, implies that where only one fixed screen is in use there should be (for daylight) four thicknesses of paper and two of glass. In this case, however, one thickness of a somewhat darker glass will do instead of the usual lighter green, or one of the light green and one of the ordinary orange pot may be used; but in this case the light is not so agreeable.

It is very difficult sometimes with those who have made a study from such writings as have appeared on the subject of the effects of light and different colours upon sensitive substances—and they are rather voluminous—to shake the ideas which this study has instilled. I have just met with an instance of this in the case of a gentleman well known as a photographic experimentalist. He told me that upon receiving the samples of glass and paper which I sent him he had examined them with the spectroscope, and that told him they were worthless for the purpose proposed, so he laid them aside. Afterwards—putting them to actual trial—he had been surprised to find the difference between the resulting facts and the conclusions he had arrived at from spectroscopic examination. Does this prove that the spectroscope is an untrustworthy instrument? Not at all. Or that, as is sometimes said—"Theory says one thing, but practically the facts are the other way?" It only proves that the theory which is contradicted by facts is an unsound one, and had better be amended or replaced. How an unsound theory acquires such general acceptance is another matter; but when a conclusion is found to be erroneous it is well to investigate the premises on which it is based, and to see whether in this case the facts of spectrum photography and of the photographic power of rays of different colour upon sensitive substances have not been incorrectly described by those whose authority has been accepted on the subject. As a matter of absolute fact, in safety of working light Mr. Cowan's experiment, in which he held a rapid commercial plate close to a light which was considered ample for working by for a period of fifteen minutes without getting any deposit upon development, is, I believe, unprecedented. However much it may contradict theories built upon mistaken premises, it should be remembered that this safe light was yellow; whilst the combination of ruby and orange, which the same experimentalist formerly used, gave a deposit on the plate with only five seconds exposure, without, as he stated, affording so much light to work by.

I have frequently been asked what is the object of the addition of the green glass to the yellow paper. When several thicknesses of any clear, deep yellow medium are employed the light transmitted appears orange, or even almost red. A solution of bichromate of potash in thin and thick layers is a good example of this. The green seems to restore the yellow character of the light, and at the same time it cuts off a good deal of light of some actinic power, whilst it does not much lower the luminosity to the eye—the visual power by which we work. W. E. Debenham.

P.S.—I do not propose to follow Mr. Starnes into his curious speculations about "wave-lengths," further than to say that if he objects to the absorption theory regarding coloured media on the ground that no discoverable work, such as expansion or chemical work, has been done by the light, this objection would hold with greater force in the case of an opaque or black body, where the whole, or nearly the whole, is absorbed, and a greater effect, such as of expansion, &c., ought to be observable. Or does he suppose the light in this case also to be merely changed, and that black rays are transmitted or reflected, as the case may be? The idea of rays being changed into others of different wave-lengths by transmission through a coloured medium is one which at present must be con-considered as a mere guess with all the evidence against it. If any evidence in its favour should be forthcoming it will, doubtless, be well considered.—W. E. D.

THE CAMERA IN WAR: A RECOLLECTION.

You had an article about the camera in war, on which subject I can tell you an amusing story. In 1861 I was at Naples with a camera trying to get some good photographs. An old schoolfellow and friend, Lord St. Maur, came out there to join Garibaldi's English legion, and I was, therefore, able to get about pretty well where I liked. One morning four of us drove out from Naples some twelve miles, where a battle was expected between the Neapolitan troops and the Garibaldians. The party consisted of Lord St. Maur, Frank Vizetelly (lately killed with Hicks Pasha), Colonel (now Pasha) V. Baker, then of the 10th Hussars, and the writer.

Suddenly, having been some time within range, on turning a corner of the road we saw in front of us a thin line of some twenty or thirty Garibaldians, with "Garibaldi's Englishman," Colonel Peard, at their head. They were slowly retreating towards us, a regiment of Neapolitan cavalry being barely kept at bay owing to Peard's men being very short of cartridges. Peard hailed us as an available reinforcement. As I thought it a fine chance of getting a picture of a regiment of cavalry charging, out came the camera, and we joined the line. What the cavalry thought I know not, but they charged at once. We all stood our ground till they were within an easy distance, and then gave them a simultaneous volley. This and a strong reinforcement of Garibaldi's own men, who came running across the fields at the moment, upset the cavalry, who actually reined up, turned tail, and fled! (Poor Frank Vizetelly sent home a picture of the affair, which duly appeared in the *Illustrated London News;* and, our names having been put under our respective portraits, Colonel Baker and myself were called to account by the War Office.)

We had a narrow escape of having to walk back, as a half-battery of artillery who were supporting the cavalry had managed to send a round shot clean through the back of our carriage. The coachman ran away; but, luckily, the horses came trotting up the road towards us, and we managed to get hold of them.

But the amusing part is that one of the Garibaldian officers, who had come up just before the cavalry retired, was greatly puzzled by the camera. A few days after he came up to me in the streets of Naples, and begged me to tell him what sort of gun it was I had driven off the cavalry regiment with. At first I could not get him to believe me; but when he did see I was really serious in telling him it was nothing but a stereoscopic camera, and that I had got a capital picture, he remarked, as though he was saying something that explained it all—"Ah! then you must be an Englishman!" He seemed to think that accounted for any act of folly.

I got some very good pictures of the battle-fields at that time—most interesting and instructive, and not the least so was the one of the smashed panels of our carriage! I was using then Hill Norris's plates, and very good they were—better than some I made myself with a gum-arabic preservative, though the year before I had got very good pictures in India on such plates, of my own make—not an easy thing in those days for a young amateur to do. I had been stirred up to photography by Mr. Roger Fenton when in the Crimea. I still have somewhere the pictures taken by him of my hut, in which I spent eleven months before Sevastopol. *Eheu! fugaces anni!* H. STUART WORTLEY, *Colonel.*

STANNOTYPE.

No. IV.

The next step is the sensitising of the tissue—an operation which does not differ materially from the sensitising of ordinary carbon tissue, except in so far as the greater thickness of the gelatine sets up a different state of affairs.

As a matter of course, in order to render the layer of gelatine sensitive throughout its whole thickness, it is necessary that the bichromate solution should thoroughly penetrate it—not necessarily during the time the tissue is actually immersed in the sensitising bath, but at anyrate by gradual diffusion afterwards, during drying. It is a well-known fact to chemists that chemical action proceeds in the same manner—though not so rapidly—in a solid jelly of gelatine as when the latter is in the liquid state; hence, though the brief immersion of a few minutes may be insufficient to penetrate the thick "relief tissue" and cause it to become "limp," if there be sufficient of the sensitising salt absorbed at the surface it will, in course of time, spread itself through the thickness of the layer.

It is, of course, possible to allow the tissue to remain in the sensitising bath for a sufficient time to cause the solution to penetrate it thoroughly; but then another difficulty arises: the quantity of water absorbed is so great that the drying of the tissue is greatly delayed, and, in consequence, the chances of insolubility—partial or total—greatly increased.

The quantity of bichromate actually absorbed by the film of gelatine has an important bearing on the sensitiveness of the tissue. With the comparatively thin layer of ordinary carbon tissue little trouble is experienced in this respect, as a brief immersion in the ordinary five-per-cent. solution is sufficient to thoroughly imbue the whole mass. But when we come to deal with a thickness many times greater, and have at the same time to avoid as far as possible the absorption of too great a quantity of water, it becomes necessary to consider which is the best method of procedure. An immersion of three minutes in a three, four, or five-grain solution of bichromate suffices, even in cold weather, to render ordinary carbon tissue perfectly "limp"—the test usually adopted of complete sensitising. But with the much thicker relief tissue such a period of immersion is in every respect inadequate; and when extended to five minutes it is necessary to employ a solution of the full strength named above, in order to secure a thorough penetration of the film of gelatine and a proper degree of sensitiveness.

As regards the physical conditions of the stannotype tissue we are fortunate enough in finding it—if prepared according to the directions given in the previous article—in a condition which renders us independent of any consideration of its "limpness" or otherwise after sensitising. Stripped, as it is, from glass, and kept under pressure, or at anyrate flat until the time of sensitising, it does not present the same difficulties in the performance of that operation which the carbon tissue supplied in rolls does. We may, therefore, be satisfied with a short immersion, provided the sensitising bath be of an appropriate strength, trusting to the complete diffusion of the bichromate during the subsequent period of drying.

For ordinary use the five-per-cent bath may be used, or, as it is generally stated, one ounce of bichromate of potassium to one pint of water. This must be filtered and kept perfectly free from dust or other matter, which, if it attach itself to the surface of the tissue, will inevitably produce defects in the resulting relief. The dish in which the sensitising is effected must also be kept scrupulously clean for the same reason. The tissue is immersed for five minutes, and the surplus solution then removed from both back and front by means of a fine sponge or a pad of linen free from "fluff." It is then ready for drying.

This portion of the operations requires more attention and care than is usually given, or than is necessary with ordinary tissne. The great thickness of gelatine necessarily causes a larger absorption of solution, and consequently there is a larger quantity of moisture to be got rid of. In addition, there is a stronger tendency on the part of the tissue to curl up in drying. To avoid the latter difficulty it is usual to tack the damp tissue on to a wooden frame large enough to leave both sides open to the atmosphere in order that evaporation may go on from both sides. If such frames be not at hand, a substitute should be extemporised by tacking strips of wood to the four edges or sides of each sheet of tissue, in order to prevent as far as possible the warping and curling which would otherwise occur in drying.

From what has been already said it will be recognised that under any circumstances the drying operation is longer than with ordinary tissue, and that, therefore, it is desirable to hasten or curtail it as much as possible. The application of heat for this purpose is available only to a slight extent for two reasons: its tendency to liquify the moist gelatine film, and, on the other hand, to induce partial insolubility when dry. The chloride of calcium drying-box is, therefore, a great convenience, and, indeed, where much work is done, an absolute necessity. The object to be held in view is to dry as rapidly as possible *without heat*, or with the application of as little heat as can be conveniently managed. The longer the gelatine remains in the moist state after sensitising and the higher the temperature the greater is the tendency to insolubility. This insolubility may not be absolute, but according to its degree it will render the subsequent development of the relief more difficult and tedious.

It has been proposed, in order to increase the sensitiveness of the tissue, to employ a very concentrated solution of bichromate for sensitising, with a view of causing the absorption of a larger quantity of the salt with a short immersion. In making the tissue on a large scale, and with perfect appliances for rapid drying, the bichromate is mixed with the gelatine; but this is scarcely practicable on a small scale for the reasons that we have mentioned—the tendency of the tissue to become insoluble if the drying period be protracted. We have used a ten-per-cent. solution of bichromate, but cannot recommend it for general use, as whatever gain there may be in rapidity of printing is more than counterbalanced by the greater trouble in development, owing to the "insolubilising" effect of the stronger bichromate solution. The five-per-cent. solution is the best for general purposes.

SINGULAR LUMINOSITY OF THE ARGENTIC-BROMIDE GELATINE FILM.

Some time ago my attention was much attracted by the note recorded in these pages respecting Captain Abney's observations on *Shearing Stress*, and as to the fact that, in cooking emulsion, if the same were stirred in the dark a luminous appearance resulted. What the character of this light was—whether fluorescent, phosporescent, or the light usually attending electrical activity of high tension—I do not remember to have seen made the subject of comment, nor do I intend here to offer any opinion on its character, though I am inclined to think it is of an electric nature, similar to that produced when pieces of sugar are rubbed together.

Not long after reading the observations alluded to I was charging my slides, and I use a good strong light (a paraffine lamp behind two thicknesses of stout orange paper oiled). The plates I was using (the Albert) were separated by four small pieces of thick paper placed at their margins. One of these pieces of paper adhered somewhat strongly and resisted a hard rub, so that I had to pick it off with my nail, when at the moment of parting from the film there was a very bright, somewhat greenish-blue, light emitted, which much puzzled me as seen in the full light of my lamp. At that time I could not succeed in reproducing this light, as the other pieces of paper were less adherent.

I thought much on the subject, and almost came to the conclusion that I must have had a fragment of phosphorus from a lucifer match on my nail, and that this had caused the light, for it was very similar in character to that produced by scratching the top of a match; but I was unable to reconcile the silence of the discharge and the colour with phosphorus being the cause.

A few days ago I was tempted by the improved light of the last few weeks to refill my slides, and, using the same plates similarly separated, I tried if the light I had observed on the former occasion could be produced at will. I wish now to record that whenever the pieces of paper adhered pretty strongly and I briskly scratched them off with my nail I was able to again produce this singular light, though never again nearly so brilliantly as on the first occasion, and I have fancied with not quite so yellowish or greenish a tinge. The surface showed a slight disruption of the film where the pieces of paper had been scratched off when the light was produced.

My experiment was with a dry film; the earlier note recorded in these pages was with emulsion. There is, therefore, a little difference in the circumstances attending the two cases. I did not notice that when developed the silver was reduced where the light resulted, but it may have been.

The unstable equilibrium of cooked Ag Br may possibly be upset by friction as well as by actinic energy, and we know that all chemical action is accompanied by electrical disturbance. The explanation may be found in this, but I would rather have others to explain while I record, as the subject is at present in my own mind inexplicable. H. H. Cunningham, B.A. *(Cantab).*

SULPHITE OF SODA IN THE DEVELOPER.

May I ask space for a few remarks in explanation of some of the terms used in my former article on this subject? In speaking of "clear glass in the shadows" I intended especially to refer to the absence of the so-called "pyro. stain" in the more transparent parts of the negative. With regard to the "non-actinic colour of the deposit," exception has been taken to this term on the ground that the colour is due to the above-mentioned staining of the film, and not to the actual colour of the deposit. That this is not the case is readily proved by the experiment suggested. It will be found upon trial that it is quite impossible "to produce a similar non-actinic colour in an oxalate-developed negative, subjected, after fixing, to a bath of alkaline pyro." In this case the film will be stained, but for all practical purposes the colour and printing value of the deposit will remain the same.

Mr. S. Fry is correct in stating that the colour of the image in sulphite-developed negatives more nearly corresponds with that of the retouching pencil. I quite admit that from such negatives an increased number of prints can be made in a given time; but I fail to see the advantage of producing a larger quantity of prints without regard to quality or permanence.

In expressing my views on this question I have assumed, perhaps rashly, that any slight saving of time in printing and retouching, or even the "one greatest charm of delicately-clean figures," so eloquently eulogised by Mr. Fry, should be deemed of minor importance, and scarcely worth consideration as compared with perfection of results. As regards actual development: in my own practice I have always found that all that can be done with the sulphite developer can be done quicker and, I think, very much better without such addition. I am, therefore, surprised to find it stated by Mr. Fry that the pyro. developer without sulphite of soda "becomes at once, on mixing, thick and turbid, throwing down a solid, opaque deposit when the ammonia and pyro. come together." This is quite contrary to my own experience and that of others. There must be something radically wrong in Mr. Fry's manipulations or his chemicals, or possibly in the water he uses, to produce such a result. A solution of fresh pyro. in distilled water containing a trace of citric acid becomes only slightly discoloured on the addition of the ammonia and bromide. It will gradually become darker in colour by keeping, but should remain quite free from deposit; and, although slower in its action, will retain its power of development for a very long time. At a recent meeting of the Photographic Club several negatives were shown which had been successfully developed with alkaline pyro. mixed as above, the developer having been previously used for eight negatives in succession, and kept for twelve months after mixing.

It is possible that the success of the above experiment may have been in some measure due to the small quantity of citrate of ammonia formed in the developer. I would, therefore, suggest, in making comparative experiments to determine the utility of the sulphite, that the required excess of acid be mixed with the pyro. solution, and the same tested with and without the addition of neutral sodic sulphite in various proportions. If tried fairly it will be found that the gradation and printing qualities of the negatives will improve in proportion as the quantity of added sulphite is diminished. B. J. Edwards.

ONWARD!

It behoves thinking men, every now and then, to stop a while in the course of their progress to take a view, philosophical it may be, of the state of things in a given way; examine, with some care, to get a definite idea of the subject under contemplation; and, if advisable, to communicate the impressions left on the mind to those whom it may interest. This is the case with me, and I now purpose laying before the reader the impressions left on my mind by a survey of the photographic work recently produced, or with which, at anyrate, I have come in contact.

I began by asking myself whether much progress had been made in photography within the last five years, and an affirmative answer came forth, on recollecting that five years since a new era was opening; a fresh system of working was steadily forcing its way in hands and minds; that dry-plate work, in the garb of gelatine, was to be the system of the future, to the abandonment of the "messy" old wet-plate process. Difficulties in the working had successively to be overcome; simplification in the manipulations secured; a more accurate knowledge of the power of the new servant attained; and what instruments were preferable in conjunction with it. Although improvements will to a certainty be yet made, it must be acknowledged that the present condition of gelatine working is very satisfactory indeed. Speed to a very great extent; swallows taken on the wing; Neptune's vivid embrace of *terra firma*; topographical views of towns from the trying cars of balloons; man and horse vaulting over gate—features of rider made out—all this speaks for itself. Lenses, too, keep pace with the times; they will do what is required of them in nineteen cases out of twenty, and do their work wonderfully well.

Now come manipulations proper; and here it may honestly be said that the photographic body work to perfection. No more marble stains, no nasty patches, no grubby-looking pictures. Even printing is well understood and carried out, and the results are uniformly satisfactory. Some still produce prints more juicy and mellow than others; it is their privilege, since their discriminating eye shows them it is best so. The lessening of the weight of the *impedimenta*, also, shows progress. The neat and light pocket camera is a gem, as well as the symmetricals, be their denomination what it will, so long as they emanate from an able and reliable worker. With the exception of the stand, one may go out unnoticed, yet really carrying three dark slides, 5 × 4 camera, and lenses, without in the least attracting attention. Surely these are golden days—days such as Rejlander would greatly have relished, fully appreciated, and to which he would have done justice.

And what about the work *per se?* It is unquestionably good in the large majority of instances. Better judgment is clearly discernible, more taste, a better realisation of what goes to constitute a picture, and a laudable aim much more frequently seen. Landscape especially is admirably rendered, and so is the sea and its associations. In both a large number of representatives may justly be regarded as no mean adepts, and in wishing to pronounce who is really best one is often greatly embarrassed. Portraiture appears to have been treated in almost all conceivable ways, and wonderfully mastered by some. In composition work, however, very few indeed can as yet be said to have succeeded; this is the *pierre d'achoppement*, or stumbling-block, over which the daring, but improperly-trained athlete comes to grief, furnishing the bystander the poor satisfaction of witnessing the imperfectly-measured leap and melancholy fall. As yet very few have successfully vaulted over the perilous chasm, and they form a tiny cluster arrayed in their picturesque costumes and with miens worthy of true champions. They are now taking breath, preparatory to furnishing all with some new performance that shall eclipse their previous performance, and, if possible, that will gain them preference over a contesting rival. This is most laudable emulation.

But to work—to the purpose—that I may not be deemed slumbering, and ranked among the drowsy old fogies who lull you to sleep with their dreary talk. Has progress attained its limits? Is there no further room for perfectibility in the photographic work of the day? Indeed much is yet to be attained by the ambitious; a far closer study of nature—of the work of the select *élite* of photgraphers; a much more intent study of what constitutes art proper; a realisation of the ideal; the cultivation of the truly poetical; and, finally, the manner—a way, in fact—to the realisation of all this.

What is the fault of the day—the glaring fault—which causes men of art-culture to turn from photography? The very general want of perception of the poetical, and the knowledge to suitably render this? Photography, as practised by tens of thousands of votaries, is graphically perfect. It is precise, mechanically correct, and incisive. It pierces and cuts; it stares; it has the keen edge of the razor. Slightly mitigated, it loses its offensiveness, becomes placid, and is a quiet friend one takes a walk with, with no positive objection, if with no actual thrill of pleasure.

Then, what is to be done? How is further mitigation to be understood, that the friend may become a really sympathetic one? By seeking to throw into the work that mysterious halo peculiar to genuine art—that poetry which alone can satisfy the true *dilettante*—that is the only way. Is this easy? The query is very pertinent—the reply "yes" and "no." It is easy when innately feeling what is wanted, what constitutes the truly beautiful; but it is absolutely impossible for those to whom this fine gift is denied, and which may be summed up in seeing, feeling, and penetration, with ability to render. That these terms should be to some extent abstruse is not to be denied; perhaps they might form a profitable theme to meditate upon.

Now for examples. Proceeding from the comparatively simple, I shall first take up the portraiture of the day. Side by side with others recently stood a collection of the works of Mr. Mendelssohn; next to his, notably, the work of an otherwise good photographer. From a few yards' distance I cast an alternate glance at the productions of the two, and not a minute's hesitation remained on my mind. Mr. Mendelssohn's pictures possessed art and poetry; his competitor's none whatever. In the latter the lines were harsh, the lights staringly white, the shadows decidedly black; in the former a softness of light, line, and tints, besides capital posing and lighting, made it manifest that a masterly head and hand had the making of the pictures. Mr. Faulkner from the first sought the beautiful, and to the last renders it felicitously. His productions evince taste, culture, knowledge, and sterling ability. They are never monotonous, never harsh, never unsuggestive, never done to death, never stagey—*à bon entendeur, salut!*

In landscape a vast deal of really excellent work comes yearly to the front. Seen individually or collectively the pictures are good—mostly well chosen, neat, and pleasing. A strong affinity is manifest in the productions of many workers living far apart and unknown to each other oftentimes; but they use the same type of lenses, stereotyped sizes of plates, develope and treat in a manner somewhat identical, and only differ in the views taken. Here and there someone will soar higher—as does Mr. W. McLeish—distinguish himself at a stroke, and carry off the coveted laurels, which he (Mr. McLeish) well earned. Somehow, there is something finer to be done than the work of the man whose work resembles other men's work. There is something infinitely superior in every respect, and that is work such as Mr. H. B. Berkeley recently had at an exhibition. Now with his productions I have every sympathy; it is my ideal of what the sort of work should be. It is as beautiful as the finest etching; possessed of the same delicacy; and each production, taken individually, is a gem. Here size has nothing to do with the matter, for I doubt their much exceeding a half-plate. No; the whole thing lies in the mode of treatment and finish. I sincerely wish I understood platinum printing as that gentleman does, and if I wished to follow any one I would certainly follow him. Then there is art, and, next, higher art still, even in landscape. Yes, and this is simply unquestionable.

But it is to composition work I must now revert—to the forming of a picture that will convey a thought, because of its characteristics as a subject and mode of treatment. The first thing I would strongly impress on the mind is the twofold aphorism "*ars probat artificem,*" and "*ars celare artem.*" They are distinct, and, withal, play into each other's hands. Those round whom the *Venus de Medicis* was produced were right in propounding these phrases to guide the artist in his work—to remind him of "the art to conceal art." There is an infinite deal in that. The highest and best photographic instances of this, to speak of the pictures of the day, are to be found in Mr. Adam Diston's *Industry*, in his *Gloamin'*, and *After the Storm*. He understands how to conceal the manner by which he proceeds. He knows the value of concentration of light. He possesses the skill to effect this. How to subdue parts, so as to make them unobtrusive in his work. You want delineation perfect; he will furnish you with it wherever necessary, and nowhere else. The accessories are simple, natural, not over-prominent, *ad rem;* not overcrowded, not too sparse, retiring where need be, a little more forward when of importance, and withal perfectly subordinate to the figures. The last are simple, characteristic, interesting, eminently human, possess feeling, and are sympathetic. In all three subjects named the figures are striking amid the quiet of the surrounding tones. Even on the very bust of the two first a soft harmony pervades; there is tone on them and in them. Isolate any one of these three pictures; stand back a couple of yards, screen all things surrounding with your hands spread outwards from your eyes, and look. Look well, read intently, and the small personages delineated by Mr. Diston will grow in magnitude; life will permeate through the soft tones; real live figures will stand before you, till you become unconscious that you have before you only a phantasm—a reflex of the living. Look longer at it. The old figure will linger in your mind—will stamp an ineffaceable impression on your brain. You will begin to put to yourself numberless questions about the interesting figure, her childhood, her youth, her prime, the turn of life, the descent down hill; all this, with its multitudinous incidents—that which gradually sank those deep furrows in the brow of this, God's creature! When you turn away, the figure will follow you, the old soul will be your companion, you will wonder that she should have become such a friend, and wish her well from the bottom of your heart.

This is what real art alone can do. No other way is there to appeal to the sympathy. It must be realisation to the most complete extent, by means artistic, by able treatment, by judicious selection, by proper and natural choice of attitude, by degradation or subduing of tones, by the use of a suitable light, by the toning of that light so that not a crude spot remains—not a speck intrudes. The pictures are, I think, to be had. Procure and study them; ask yourself the why and wherefore of this, that, and the other. Your queries, if properly propounded, will to a certainty elicit satisfactory answers; and you will be the wiser, and possibly be put on the road to improvement over your past work. Your aim will be higher; you will no longer rest satisfied with secondary work, but wish to produce better and more perfect pictures. Were Gerard Dow alive he would delight in *Gloamin'* and in *Industry*. He would heartily shake hands with Mr. Diston, and acknowledge in him a brother mind. The two would, I warrant, value and fully appreciate each other's society—the themes would be in common—the chitchat delightful to both. Thus it is with men of a similar stamp, whose aim is honest and high. The breadth of their minds precludes jealousy. If they emulate each other, it is all for art's sake, and not out of mean rivalry. Thus it is with noble minds.

I trust I shall not be suspected of writing anyone up. Not one of those whose names are mentioned in this communication have I ever come in contact with, or in any way do I know. I have but one object in thus writing—the furtherance of art study proper, and the desire, all the while, to furnish hints of a nature to stimulate the worker to higher exertions; that the productions of the camera may steadily improve in character and quality; to direct the mind to rise above the tedious humdrum so repulsive to superior intellects. It is such a relief to soar in higher and more wholesome air, to be able to grasp a better and broader view of things, and to render them accordingly! Who would be a tame plainsman if he could be a hardy mountaineer and live aloft? Who would either crawl or walk if he could fly? Further study, and dare—*Audaces fortuna juvat.*

A. F. Genlain.

SILVER PRINTS.

These might be made more permanent if photographers would be satisfied with a paper having a fair surface. Pure albumen alone without the addition of other ingredients gives but a certain amount of glaze; but it ensures perfect coagulation with the silver, printing better, and making comparatively easy the toning operations, to say nothing of the worry and anxiety saved to the poor printers, who are an intelligent class, not sufficiently recognised as they should be, especially in these days of gelatine negatives.

In the matter of washing: twelve or fourteen changes, hand to hand—that is, transferring the prints, one by one, from one water to another—will do far more to remove the hyposulphite of soda than by leaving them wallowing and clinging in a mass all night.

From the very nature of the compounds used in the preparation of the highly-glazed papers, now so much in demand, instead of being a gain they are a direct positive loss, in every conceivable way, to the albumeniser as well as to the photographer and printer—by unnecessary additional labour, &c., to the former, as well as chemical action being retarded by the use of the substances alluded to, and innumerable difficulties experienced by the latter in accomplishing (which is too often the case) the production of an unsatisfactory batch of prints.

To alter all this the remedy is simple—*use only pure albumen paper;* sacrifice all else, if it be a sacrifice, in dispensing with the treacherous high glaze. If a high glaze must be had, first secure good prints; and then burnish or enamel them, which will tend further to preserve the pictures in the future.

W. H. Hunt.

CLEARING GLASS.

This title is, no doubt, sufficiently comprehensive to include all methods of getting rid of dirty glass, whether they consist in making it clean for further photographic use or in converting it into "cullet" for making paths or for mingling with the fresh charges of the glass-makers' pots. In these days of gelatine there is certainly much in the way of waste plates (*carte-de-visite* size especially) that will not pay for cleaning off; and, as most of us are averse to entirely wasting them, they are allowed to accumulate in the dark room (usually) and elsewhere on the premises of a photographer, till they become a grievous nuisance and an eyesore to anyone with the bump of tidiness and order. Nothing gives a more disreputable look to a dark room than dirty glass scattered about, the greater part of which has not been half washed and having the hypo. crystallising out upon it, so contaminating the fingers that nothing can be touched by them after they have been in contact till they have been thoroughly washed.

I have an idea which, I think, I have seen expressed in these pages, that these small gelatine plates, loaded as they are with silver, would pay a glass-maker to collect and buy up for the manufacture of that particular tint of glass so fashionable now, and which is, if not produced with silver, very similar in tint to glass having that metal in its composition. If they were of any value for this purpose the enormous number of waste plates would go far towards supplying all the materials for the manufacture of that description of glass, and would remove the greater part of the dirty-glass nuisance from the premises of the photographer. Can anyone move in the matter? Who has friends among glass workers?

All sizes above and, perhaps, including half-plates will pay for cleaning—where there are any boys or apprentices in the establishment who may be not always fully employed in winter time—if stored and done in batches. To prevent, however, the glass from deteriorating or making a nasty litter, each waste piece, when condemned, should be allowed to dry and then be stored away on a shelf in blocks of the various sizes, by rearing face to the wall, and according to the treatment they are likely to require—that is, gelatine plates, varnished films, and carbon transparencies in one part; unvarnished collodion films in another. It is far better to put them all away quite dry thus than to let them stew in their filth for weeks, or stick together and stain, till they are quite worthless in photography.

When the quiet time comes the whole may be speedily converted into a clean and useful article by proceeding as follows:—The unvarnished plates—collodion films, I mean—should be put into a crock, tub, or dish of dilute hydrochloric or sulphuric acid till the film floats off, then rinsed, and put in a tub of clean cold water. The others—consisting of gelatine plates, varnished films, and carbon transparencies—must be placed one by one on a wooden dipper, made of a lath with a couple of wire nails to rest the plate on, and immersed in a copper of strong and boiling soda water till the film dissolves off; then withdraw the plate and place it upon a piece of wood, and well rub both sides with a piece of canvas to clear away any obstinate particles adhering. Re-dip it in the copper and pass it to boy No. 2, who should immerse it in cold water and well rub it again with the fingers on both sides to remove bits and rinse off the soda before plunging it into the tub of water which has already received those from the acid. Carbon transparencies on a bichromated gelatine substratum are about the most difficult to remove. These will stand some minutes of the strong boiling soda-water before yielding. It is better not to hurry these out, but to let the gelatine dissolve off entirely. It will not rub away. Dry plates skin off at once without any trouble, and varnished wet films immediately on entering the soda water. With a couple of boys at work who are making use of three or four dippers there will be no excuse for standing idle; for while boy No. 1 is removing a piece of glass from the soda, rubbing and re-dipping it, No. 2 feeds the copper by putting another glass on the empty dipper and placing it in the water under those already in pickle.

After the whole has passed this stage, and is in the tub of water, the next operation is to get the clean but wet glass dried and stored as quickly and easily as possible. To do it with cloths is certainly one of the most disagreeable and tedious operations anyone could desire. No drying-cloths should be used. The copper must have its dirty water ladled out and carried to the waste tub for what silver there is to settle, and its place supplied with a few buckets of clean water. When this is raised to the boiling-point boy No. 1 takes a glass out of the tub, dips it with his fingers into the boiling water for a few seconds, then hands it to No. 2, who mops it on both sides with a pad of old rag or a sponge, and rears it up dry. Four or five hundred an hour may be thoroughly dried in this way.

The glass thus treated is equal to new, and may be repeatedly used without exhibiting any defects arising from its having been used before; whereas, when the pieces as wasted are put together wet, the surface of the glass is immediately spoiled by the stains and tarnish proceeding from the unequal wetting. It is, besides, a marketable article now it is clean.

The value of the foregoing I am able to vouch for from my own experience. My periodical clearing-up takes place about every six weeks, after which I am able to say that I have not a piece of useless, dirty, or broken glass on the premises. As a lad I have had a hand in clearing up large batches, frequently numbering as many as five thousand pieces, the principal portion of which consisted of glass of an exceedingly delicate description, and many of which have been used in that most delicate of all photographic operations—the production of high-class stereoscopic transparencies in the camera. On the other hand, I have worked in studios where soiled glass was allowed to accumulate almost by the ton without remedy, as far as I was concerned. I hope, therefore, that these remarks may help to a riddance of the nuisance.

John Harmer.

THE UTILISATION OF THE LAWS OF LIGHT.

There are two methods of developing photographic plates:—One is by unintelligently using, always in the same manner, the illumination given by the screened window or lamp; the other is by developing with a knowledge of the laws under which that illumination is useful.

The other night the paper, green-yellow Debenham screen of my pasteboard lantern caught fire and was burnt up in a minute, because of the candle-flame being too close. A plate had yet to be developed. It was one of the Monckhoven plates, which I am using extensively, and with which I am very much pleased. As a transparency with them is printed by an exposure of about ninety seconds at twelve inches from a common candle, it was evident, according to the law that the intensity of light varies inversely with the square of the distance, that at twenty feet from the candle it would take 400 times longer to print the same image at that length of separation. I therefore went to one end of the room, while the candle was placed at the other, turned my back to the light, put the plate in the dish, developed it, and when the image was fairly out walked slowly up to the candle, finishing the development close to the bare candle flame, without fog. This may be called "development by legs and law." Except for the trouble of walking about, it raised the question whether travelling lamps are an encumbrance or a necessity.

In these operations the walls of the room took the place of the sides of Mr. Starnes' lamp. They were worse in being less non-actinic in colour, and better in being further from the source of light; but the latter influence is of much more practical importance than the former. Mr. Starnes argues that actinism is something distinct from the wave-length and periods of vibration of portions of the spectrum. Ideas should not be opposed because they are at variance with orthodox science; but those who advance such variations should, at least, print the best evidence on the orthodox side, and then oppose it with crucial experimental evidence, giving facts which can be explained by the new position and not by the old one. This Mr. Starnes has not done.

Light of certain wave-lengths probably sets up intermolecular vibration between the ever-swinging atoms of the bromide of silver, so that their affinities are weakened where light has acted. The discussion of this matter, some ten or twelve years ago, in your pages may be referred to with advantage. In some cases in time the atoms fall back to their normal position, so that the plate is ready for a fresh exposure and has lost the original image, as proved by the experiments of Mr. M. Carey Lea. In other cases, as when gelatine is present, other attractions come into play, so that the partial separation of the atoms of the molecule by light is maintained. This hypothesis of the nature of the latent image has much experimental evidence in its support, and is in harmony with the accepted laws of molecular and etherial motion.

W. H. Harrison.

NOTES FROM THE NORTH.

The versatile Mr. A. Cowan has conferred a great favour on many photographers north of the Tweed by enabling them to see his instructive series of twenty lantern transpariences printed from one negative, each differing in colour from all the rest and ranging from deep black to warm brown. There are few, experienced in lantern work, who would not pronounce each specimen seen by itself a perfect picture, and who would not, in looking at them altogether, find a difficulty in deciding as to which is best for general use. Personally I confess to a leaning in favour of those marked respectively "five" and "ten;" but if in practice it should be found as easy to vary the colour at will as Mr. Cowan believes it to be, the lanternist desirous of making his exhibitions as nearly perfect as possible will select several favourite tints and employ them with discrimination on subjects to which each is most suitable.

Exhibition of lantern pictures absolutely alike in colour, even although the pictures themselves are of the highest class, are to most people just a little monotonous; and there cannot be any doubt that a study in architecture, a sunlit landscape, and a so-called "moonlight effect" can hardly each be shown at their best if printed in the same tone.

The *developing* agent employed by Mr. Cowan is in all cases iron, and the great diversity in colour is got by additions of a few acids, alkalies, and salts, in varied proportions and quantities.

The experimentalist, however, in following Mr. Cowan's lead, must not expect to reach at once success equal to his. An examination of the instructive table of chemicals and quantities appended to the frame in which the pictures are mounted, shows that a very trifling increase or decrease in the proportions exercises considerable influence on the resulting tint; and when the unstable nature of some of them—ammonium carbonate, for example—is remembered, it will be evident that when any particular colour is required the operator must either have all his material of constant strength—and for this purpose standard solutions will be found best and most convenient—or make up his mind for a little experimenting before obtaining the desired shade.

A transparency on glass, whether for lantern or decorative purposes, has long been recognised as one of the most perfect photographic productions, and the introduction of Mr. Cowan's gelatino-chloride plates and his method of development ought to make it sufficiently popular to give work to many who at present suffer from the proverbial dulness of photography as a business.

Judging from the frequent allusions to the subject of intensification, it would seem that there are still photographers who find difficulties in the successful practice of the operation. Intensification by silver is said to result in stains, either during the operation or at some time after, while mercury is looked upon with suspicion—some declaring that the negative intensified by its aid will gradually fade, while others believe that exposure to light will result in something akin to opacity. Possibly the allegations against both substances may have some facts for their foundation; but, if so, I have no hesitation in saying that the faults lie in the method and not in the material.

In 1856 I saw (using the language of those days) a positive converted into a negative by bichloride of mercury, iodide of potassium, and ammonia, and only a few days ago it was taken out of the paper in which it had lain for eight-and-twenty years, and yielded a print quite as good as those first obtained. Several of the published methods of mercurial intensification may be relied upon as both safe and practical; but the following, which has been repeatedly described, I believe to be the best:—

A.

Mercury bichloride	1 ounce.
Ammonium chloride	1 ,,
Potassium iodide	*quant. suff.*

Dissolve the mercury and ammonium salts in ten ounces of water, putting them both in together, and add sufficient of a strong solution of potassium iodide to dissolve the red mercury iodide formed by the first additions. Then make up the bulk with water to twenty ounces.

B.

Silver nitrate	½ ounce.
Potassium cyanide	*quant. suff.*

Dissolve the silver in five ounces of water and add sufficient of a strong solution of the cyanide to dissolve the precipitate formed by the first additions, and make up the bulk with water to twenty ounces. The solutions will keep indefinitely, and where very much intensification is required should be used at the full strength; but when only a slight action is desired, A may be diluted to one-half or one-third.

The fixed and well-washed negative should be placed in a dish with sufficient of A to cover it, and kept in motion for a few seconds. Let the action proceed, examining the plate from time to time, till apparently sufficient—or, rather, a little more—density is produced. At this stage the negative will have the appearance of a rather dense but thoroughly good printing collodion image, and the operator may feel inclined to "let well alone." On well washing the plate, however, he will find the whole deposit has assumed a yellow colour, and the washing must be continued till that colour is uniform all over. When that change has been accomplished the plate must be placed in another dish, covered with B, and kept in motion for a few seconds as before. Gradually, beginning with the higher lights, the yellow will give place to a fine olive brown, and the action must be allowed to continue till the whole negative has assumed that colour. A final wash completes the operation, and I have little doubt that whoever will give it a fair trial will no longer feel that there is any difficulty in intensifying his negatives.

Regarding the practical permanence of the image thus intensified I have no doubt whatever. I have practised the matter pretty constantly during the last two years, and there lies before me while I write a negative of the birthplace of the late Dr. Moffat from which some hundreds of prints have been taken, and it is, so far as it is possible to judge, absolutely unchanged. JOHN NICOL, Ph.D.

THE BEST METHOD OF PRINTING.

THE best method of printing upon albumenised paper is to float for one minute upon a solution of nitrate of silver forty-five grains to each ounce of water, draw the surface of the paper over a glass rod, and then lay between sheets of clean blotting-paper. By these means the whole of the sheet is uniformly sensitised, which is not the case if the sheet is suspended to dry directly it is withdrawn from the silver solution, as the lower portion must absorb more of the silver solution than the upper; and the longer the paper is in drying the greater will be the difference between the upper and lower parts of the sheet.

The sensitive sheet, being carefully blotted, may at once be hung up to dry, which operation ought to be conducted at as high a temperature as possible; when dry, expose to the action of the fumes of ammonia in a box made as follows:—Procure a packing-case 24 × 20 × 15 inches deep, with a good fitting lid, two inches from the top bore five holes on each of the sides of the box and three on each end. Now pass a long piece of string through one of the holes and out of the opposite one, so as to form a sort of network, the strings from the holes in the end crossing those from the side, and on the bottom of the box place a sheet of white blotting-paper.

Now, for fuming the paper:—Sprinkle about half-a-drachm of liquor ammonia upon the blotting-paper at the bottom of the box, place the sensitive paper face downwards upon the network of string, and close the lid. The time the paper is to be exposed to the fumes of the ammonia must be varied according to circumstances. In damp weather ten minutes will be sufficient, but in dry weather twenty or even thirty minutes will be better, this being, of course, for good ordinary negatives; but for hard and long-printing negatives the longer time *must be given* to secure the best results.

With ammonia fuming it is useless to expect the best results if the paper be floated too long, as there is then a tendency to flatness and slowness in printing; therefore do not float more than one minute on a strong bath (forty-five grains), or one and a-half upon a weak solution (thirty grains). In floating, remember that each sheet takes up a certain amount of silver, and that the last sheet before strengthening must have a longer floating than the one sensitised directly after strengthening.

For the preparation of sensitive paper that will keep, float for two minutes upon a sixty-grain bath; place between sheets of blotting-paper, dry, and then float, *face up*, upon a five-grain solution of citric acid for one minute and again dry. Just before use place in the fuming-box. But, as far as my experience goes, Mr. V. Blanchard's formula is the best ever published for ready-sensitised paper, as it is the only method that yields prints with the same surface and brilliancy as freshly-sensitised paper.

For those readers who have not seen this formula I here append it:—Prepare a silver solution sixty grains to the ounce, and be careful not to allow it to sink below fifty grains to the ounce. For each ounce of nitrate of silver used add ten drops of a saturated solution of citric acid; then add nitric acid drop by drop until the slight precipitate of citrate of silver formed is just redissolved. Float from two to three minutes, and after removing from the solution place the sensitive sheet between sheets of blotting-paper, which may be used over and over again until the power of absorption is destroyed, when, of course, it will be a valuable addition to the residue basket.

Now, about washing the prints before toning. Whether using freshly-sensitised paper or that prepared for keeping, to get the finest tones the whole of the silver must be quite removed. This can only be done by thorough washing in many changes of water, and then, but not till then, immerse in a very weak mixture of water and acetic acid (just sufficient acid to taste and no more), after which give a change or two of clean water. Tone in an acetate bath, allowing one grain of chloride of gold for each sheet of paper, and use fresh bath (not freshly prepared, but twenty-four hours' old at least), throwing it into the residue when it has done its duty.

When the prints are toned place in a weak solution of salt and water, and, if of the proper depth, give a change or two of water before placing in the fixing bath; but those prints that are too dark transfer at once to the hypo., which will to some extent remedy the over-printing. Do not allow any of the salt and water or hypo. to come in contact with the toning bath, otherwise it will be spoilt by the hypo. and stopped in its action by the salt and water.

Let the hypo. bath be made fresh each day for the prints, then be used for fixing gelatine plates the next day, and placed in the waste tub for reduction. Have a piece of carbonate of ammonia in the hypo., keep the prints moving all the time, and after fixing give at least ten changes of water at once before leaving in the washing tank.

"Gur."

ON THINGS IN GENERAL.

Well thought out, lucidly expressed, and full of true feeling for art, was Mr. Hume Nisbett's paper—*Camera Lucida, Paletta Obscura*, &c. —read before the Edinburgh Photographic Society. It was a most interesting and valuable contribution to photographic literature, and one which I advise all subscribers to this Journal to read, if they have not already done so. It is valuable to amateur and professional photographers alike, and contains many bright thoughts they may peruse with advantage. I must take exception to one little fly in this pot of honey, in that he says—"Photography is most to be relied upon for truth in all *except perspective*." Photography, I may observe, for the twentieth time, is *not* necessarily false in perspective, though it may be made so; but a good photograph, if rendered so transparent that objects beyond it could be seen, would, if held at a proper distance between the eye and the view it represented, accurately and exactly coincide line for line, point for point, with the lines and points of the scene depicted, and would be identical with a picture drawn in accordance with recognised mathematical modes of representing objects in perspective. Many photographs include a wider field of view than a painter would depict, but that fact does not touch the argument.

Another capitally-useful paper is the gleaning the Editors have made from *Autotype Notes* in the shape of the article, *Copyright Law in Brief*. It forms a short digest of the law relating to copyright, but fails in exactitude in at least one place. I point out the place in order to render still more valuable this useful "brief." At the end of paragraph 13 occur the words—"Illicit copying of an original work before the copyright is registered is actionable." Now, though a special meaning may be intended to attach to the word "illicit," the sentence, on the face of it, is contrary to paragraph 2 of the Copyright Act, which says—"Nothing herein contained shall prejudice the right of any person to copy or use any work in which there shall be no copyright." Further (I now write subject to correction): is the "brief" correct in stating that in the case of a photographer taking the portrait of a person of eminence (he presumably not paying for it), that particular person must sign an agreement? (What agreement, by the way?) Does not the Act require the agreement to be made with the first purchaser of a print of the picture? I write now purely to elicit information from the Autotype Company or anyone else. In the case of a view of a building, for instance, would not the first purchaser be the one to sign the agreement? Also, I would like to ask: Is not this point of view sometimes lost sight of—at anyrate with inanimate objects?

There is a fine point raised in the new *Notes and Queries* department of the Journal—a most useful institution, I am inclined to think, with a journal of so widespread a circulation as The British Journal of Photography. An inquirer wishes to know whether he would infringe the law of copyright by taking engravings from a book, pasting them on glass, and using them in public as magic lantern slides after rendering them translucent. It is indeed a very nice point, and worthy of the subtlety of a Q.C.

Another point about which there can be no doubt is raised by another correspondent, and reveals a state of mental turpitude I had hoped, for the credit of the profession, did not really exist. A third-rate photographer employs a first-class operator, sets him to work to make a collection of fine specimen photographs, and then—sends him about his business. The degrading meanness of such conduct is beyond the power of words to describe.

I was interested to learn, from the pages of The British Journal of Photography, that the British were going to carry war into the American camp, and start dry-plate making in the United States on a large scale. Naturally I wish my countrymen every success; but when, with labour at the price it is, and foreign materials, glass, &c., subject to the high duty there required, we see plates now sold at a price little exceeding English rates, I cannot but think the syndicate will have their work cut out. Will the next syndicate be one for the manufacture of lantern slides, I wonder? It should have good promise of success.

Mr. S. Fry says, in his article on the use of sulphite in the pyro. developer, that one of its greatest charms is "that the most delicate fingers are kept perfectly clean." My fingers would not be called delicate; yet, whenever I go in for developing and wetting my digits with the solution (with plenty of sulphite in it), they get stained with a horrible pale brown, which is as difficult to get rid of as the old silver developer stain.

In reading the report of the Photographic Society of Great Britain I noticed that there had been so much application for space at the last exhibition that it had been found necessary to reject many pictures. Yet the hangers live to tell the tale! How they managed to survive after being compelled to gaze upon photographs worse than some that gained admission is an inscrutable mystery!

The question of dark-room illumination is undergoing a thorough examination, and good will come of it. For a scientific mode of arriving at the best light for the purpose I am much pleased with Mr. Macdougald's diagram, as recently depicted in the Journal (page 103). Properly carried out, there is contained in it the germ of great usefulness.

The thanks of the photographic community are due to Mr. F. A. Bridge for bringing forward, at a late meeting of the South London Photographic Society, the subject of *Willesden Paper*—a material which is too little known at present, but which is calculated to subserve a variety of most useful purposes in connection with photography and photographic operations.

At another society (the Coventry and Midland Photographic Society) an interesting experiment with the oxymagnesium light was carried out—a kind of proceeding calculated to convey more instruction than the most learned of papers or lectures. Portraits and groups were, with the aid of this light, taken and developed upon the spot; and although the results showed the need of more complete diffusing and reflecting arrangements, a notable proof was offered of the possible usefulness of this method of artificial illumination. The published description, however, of the lenses and stops is decidedly "mixed," to say the least of it. A single landscape lens, with No. 2 U.S. stop and eight seconds' exposure, was a failure on account of the "size of the stop and the slowness of the lens," yet with a No. 10 stop and twenty seconds' exposure a "decided success" was obtained. Seeing that this should have had eighty seconds for an equivalent exposure, one is inclined to ask "why is this thus?"

It would seem that the more exalted the position of a periodical the more liable it is to be occasionally hoaxed. Everyone remembers the story related—of the *Athenæum*, I think—where a deceased *savant* was gravely described as having arrived at the "quadrature of a circular arc, and discovered the exact solution of a lunar caustic—a problem which," the paper went on to state, "was likely to be of great use in nautical astronomy." This occasion *The Times* seems to be the victim, and it has been describing for the benefit of its readers the details of a balloon to be used in an ambuscade, and which is provided with the new electro-magnetic balancing bar, which prevents the balloon from gyrating, and it is expected will be the means of eventually dispensing with ballast! I have not seen the account in that paper; but I have been credibly informed that it is there to be seen.

The Editors are careful to say they are not to be supposed "to endorse the speculations put forth in Mr. Starnes' interesting article." I think the disclaimer quite unnecessary. As to the article itself, I seem to have read something very similar in effect by Mr. W. Harding Warner some time since.

Free Lance.

FOREIGN NOTES AND NEWS.

The First Paper Photograph in Berlin.—Photographing a Flash of Lightning. — Daguerre *versus* Niepce. — Changing-Boxes. — Flexible Supports. — Twenty-first Annual Festival of the Berlin Photographic Society. — Correction. — Dr. Eder on Development of Gelatine Plates in Tropical Regions.—At too Close Quarters with a Turbulent Sitter.

The *Mittheilungen* has lately made the interesting discovery of the first paper photograph which made its appearance in Berlin. Though the Talbotype process was discovered in 1840, it was some time before it was much worked on the continent; but in 1842 Mr. Fox Talbot taught his new process to the eminent Egyptologist, Professor Lepsius, who hoped to be able to employ it in an expedition to Egypt, upon which he was about to be sent by King Friedrich Wilhelm IV. The intention of taking Talbotypes in the course of the journey through Egypt was unhappily frustrated by the breakage of the apparatus; but before setting out Professor Lepsius took a portrait of the poet Thomas Moore, which he still has in his possession, and considers it the oldest paper photograph in Berlin.

According to the *Weiner Neuen Frien Presse*, as Herr Hänsel was photographing a landscape there was a flash of lightning, and the flash was photographed along with the landscape. Its outline was distinctly recognisable on the plate, as well as its contact with the earth. Computed from the picture, its length was about 1,700 metres. The zigzag flash lately photographed by Mr. R. Crowe was supposed to be about twenty-seven metres.

On the pedestal of the memorial recently erected at Cormeilles to Daguerre is the inscription—"The Discoverer of Photography." The town of Chalons-sur-Saône now intends to erect a memorial to Nicéphore Niepce, who was born there, and the *Moniteur de la Photographie* supposes that this second tablet also will be erected to the memory of the "discoverer of photography." In inquiring how these conflicting claims are to be reconciled, the *Moniteur* would like in some way to indicate that though Daguerre had most to do with the working out of the process, yet Niepce was the real discoverer—a fact we are apt to forget. Probably the name of "Daguerreotype" having been given to the process has kept his name fresh in the memory, while, as we do not speak of Niepceotypes, the name of Niepce has fallen into undeserved desuetude.

Amongst the German patents recently applied for or obtained is a method of constantly regenerating the ferrous oxalate developer, by Dr. T. Kötteritzscha; flexible substitute for glass for negatives, by Herren Fickeissen and Becker; and changing-boxes, by Herr Mader. Herr Mader encloses each dry plate separately in a thin, light-tight tin or sheet-iron shell for a covering, one of the sides of which can be pulled up like that of a dark slide, for which it may be substituted; yet each plate with its shell occupies little more room than a bare plate. The plates so covered are placed in an ordinary plate-box, the grooves of which are widened to admit them. The plate with its metal cover is laid in a wooden dark slide specially constructed for the purpose, exposed, the metal slide shut down, and then plate and cover exchanged for a fresh one taken out of the box. The object of these covers is to do away with the use of a changing-box or for carrying about a great number of double dark slides, as the thin metal slides seem to allow of a fresh dry plate being put into the wooden dry plate about as readily as a fresh wet collodion plate used to be done, or even more readily, as, of course, the bath is dispensed with.

As flexible supports for negatives to replace glass, Herren Fickeissen and Becker use a white paper, comparatively free from texture and containing little size; they damp it and stretch it upon a suitable frame. When dry it is rendered transparent with fine copal varnish. When repeated coating with varnish and polishing has made the paper sufficiently transparent, and so hard that it is no longer sticky, some of the following solution is floated over the glass and allowed to dry, after which the paper is ready for use—instead of a glass plate—either for the wet or dry process:—Some ox-gall is mixed with acetate aluminium, which immediately precipitates the fat of the gall, so that if this mixture be placed on a filter the bitter part of the gall is obtained free from fat. When required for use some dissolved glue or gelatine is added to it. The object of this preparation is to cause the emulsion, &c., to adhere more firmly to the plate.

On the 22nd November last the Berlin Photographic Society celebrated its majority by a banquet, the chair being occupied by the President, Dr. Stolze, who addressed the meeting at the commencement of the proceedings. In the course of the evening a special journal was circulated, having a humorous title page, by Herr Bussler, and two lays by Dr. Stinde, one of which (the *Lay of Emulsion*) found so much acceptance when sung to a well-known air, that it was encored. The proceedings were terminated by a lottery, the prizes in which were various fantastic pieces of furniture and accessories, mostly droll toys.

Herr Fr. Wilde, of Görlitz, whose death was announced in many of the photographic papers for November, writes to say that he is, happily, still alive, and that the deceased is quite a different person, namely, Herr F. A. Wilde, of Halberstadt.

The sixth part of Dr. J. M. Eder's exhaustive treatise on photography has just been published. Many of our readers who are familiar with Dr. Eder's profoundly-scientific writings will be surprised to learn that he is still quite a young man, being under thirty. His first considerable contribution to photographic literature was a monograph on the double salts of iodide and bromide of cadmium, which appeared in 1876.

In tropical regions it is difficult to keep the developer cool, and the easiest method of doing so, namely, icing it, is too expensive to be much employed. The South American *Boletin Fotografico* recommends the following remedy, first proposed by the editor of *The Photographic Times*:—Take a flat bath considerably larger than that in which it is proposed to develope; cover the outside of it with felt or some other bad conductor of heat, and cover the inside of the bottom of the dish with a layer of crystals of nitrate of ammonia. Place the developing-dish upon that; fill the interval between the sides of it and of the outer dish also with these crystals, and pour water over them. When they dissolve the temperature is considerably lowered, and this coldness is communicated to the contents of the inner dish, which may either be a developer or an alum or hyposulphite of soda bath.

M. Petit has succeeded in photographing a number of wild beasts belonging to the menagerie of M. Pinnet, taking his camera with him into the cages of a leopard, a tigress, a tiger, a pair of leopards, and three lions. The tigress flew at M. Petit just as he had uncapped the lens, but M. Pinnet succeeded in calming her before she had injured, though not before she had seized, the operator. The other animals, who were afterwards photographed, proved tolerably quiet "sitters."

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

AT the technical meeting of this Society, held on Tuesday evening last, the 26th instant, the chair was occupied by Mr. T. Sebastian Davies.

As had been announced, the evening was devoted to the comparison of optical lanterns, and several members brought slides for exhibition; but as the objectives used in the various lanterns were unlike in focus, no positive opinion could be formed of the illuminating power of the instruments in use.

The CHAIRMAN opened the proceedings by describing various sources of illumination suited for small screens, and mentioned that the argand burner with colza oil, although not giving so powerful a light as the many-wick'd paraffine lamps since introduced, yet gave a more evenly illuminated surface, and for a small disc was to be preferred. He then showed a lantern of this character fed by almond oil, which, he said, gave a better light than colza, but had the disadvantage of being more expensive.

Amongst the lanterns shown was the three-wick one belonging to the Society, a two-wick one shown by Mr. G. Smith, of the Sciopticon Company, and a four-wick burner, in which the wicks were arranged like the letter W, shown by Messrs. Wood. The last-named lantern had an advantage in not showing the dark line down the centre which was noticeable in one of the others, especially when a disc without a slide was shown; but, on the other hand, there was a faint image of the four flames.

Amongst the slides shown were some illustrating the warm tones that might be produced upon gelatino-bromide plates. These were prepared by Mr. J. B. B. Wellington upon plates coated with an emulsion, the formula for which was given a few weeks since at a meeting of the London and Provincial Photographic Association. The development had been conducted with the mixture recommended by Mr. B. J. Edwards for use with chloride plates; but for warm colours varying proportions of bromide of potassium, amounting in one case to thirty grains per ounce of developer, had been added. This necessitated an exposure to a gas flame of minutes instead of seconds. The development was slow, occupying about half-an-hour; but the colour was of a powerful maroon, approaching claret. One plate that originally had been nearly of this colour showed a part changed to a cold bluish-black. This Mr. Wellington attributed to the plate having been but slightly washed after coming out of the hyposulphite fixing bath, and then being immersed in dilute sulphuric acid. On the part of the plate from which the hypo. had not been entirely removed a sulphur toning action had been set up.

Mr. C. RAY WOODS exhibited several slides from negatives taken in Egypt. He also showed a set of slides not produced photographically. These were pencil drawings on ground glass, which had afterwards either been varnished to render it transparent, or else cemented to another glass with Canada balsam for the same purpose. In order to render the glass more transparent for tracing upon than it would otherwise have been, it had been treated with glycerine and water, after a method introduced some years since by the Rev. Mr. Dallinger. When the drawing was finished the plate was washed to remove the glycerine, and then dried and varnished.

Mr. H. A. MONCRIEFF showed some slides produced by wet collodion in the camera, reproduced from larger negatives.

Mr. F. YORK exhibited slides produced upon gelatino-bromide plates and developed with pyro. and sulphite of soda.

Some collodio-bromide slides prepared by Mr. Nesbitt were thrown upon the screen, and some upon gelatino-chloride plates by Mr. Geary—reproductions of scenes in the Holy Land, taken under the auspices of the Palestine Exploration Fund Committee.

A very effective carrier for lantern slides, the contrivance of Mr. A. Cowan, was employed in one of the lanterns. This consisted of a frame with a travelling-piece. This travelling-piece was made to hold two slides which dropped into grooves. Strings led through the bottom of the travelling-piece and drew it from one end to the other, in either case leaving one of the slides opposite to the centre of the condenser. The other slide could then be changed, and a pull of the string at the opposite end brought the new one into place.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on the 21st instant, the chair was occupied by Mr. F. Piper.

Mr. J. B. B. Wellington showed a series of transparencies possessing a great range of tint, from a beautiful deep rich claret colour, through warm brown and sepia to black. They had been printed on gelatino-bromide plates, the emulsion for which had been prepared by the formula published a few weeks since. The developer employed was that prescribed by Mr. B. J. Edwards for use with chloride plates, but to this had been added, in order to obtain warm colours, varying proportions of a solution of bromide of potassium. The composition of the developer would then be—

1.	Oxalate of potash	4 ounces.
	Chloride of ammonium	40 grains.
	Water	20 ounces.
2.	Sulphate of iron	4 drachms.
	Citric acid	2 ,,
	Water	20 ounces.
3.	Bromide of potassium	160 grains.
	Water	1 ounce.

For black tones a mixture of Nos. 1 and 2 in equal proportions was used, and an exposure of twenty seconds was given to the light from an ordinary gas jet at a distance of one foot six inches. For a sepia colour the exposure had been sixfold, and thirty minims of No. 3 had been added to each ounce of developer. For claret colour an exposure of fifteen minutes, or seventy-five times that given when no restraining bromide was employed, had been allowed, and one hundred minims of No. 3 then added to each ounce of developer.

Mr. W. E. Debenham said that the obtaining of such colours on bromide plates was a remarkable step, and inquired if Mr. Wellington had tried the same development with ordinary bromide plates to see whether similar results would be obtainable upon them, or if it were necessary to make a special emulsion such as had been previously described.

Mr. Wellington had as yet only tried with the particular emulsion the formula for which had been given.

Mr. A. L. Henderson inquired whether Mr. Wellington had tried boracic acid as a restrainer.

Mr. Wellington had not done so.

Mr. Henderson continued by saying that boracic acid was the most powerful restrainer with which he was acquainted. A drop or two of a thirty-grain solution sufficed to stop the action of the developer. He then inquired whether any gentleman had tried any further experiments with canary medium. He had exposed a plate giving 16 on the sensitometer, at a distance of four feet from a screen of the medium, at a further distance of two feet behind which a gas flame was burning, for periods of from seven to twenty-two minutes, without getting fog.

Mr. A. Cowan said that he had experimented with Mr. Henderson, and calculated that at a distance of nine inches from the canary medium, with the gas flame two feet behind it, there should be no deposit from an exposure of thirty seconds.

The Chairman had tried canary medium with different results from those obtained by Mr. Henderson. He had exposed for twenty minutes at a distance of eighteen inches from the lamp, and got a weak transparency printed.

Mr. W. Coles asked whether Mr. Henderson had tried canary medium with daylight.

Mr. Henderson had not tried it fairly. He had oiled it and then it was very unsafe. The effect of oiling seemed to be to take all the green tint out of the paper.

Mr. Debenham said that the comparative safety of canary medium, as testified to by Mr. Henderson and Mr. Cowan, supported the view which he had put forth, namely, that yellow light had less photographic action in proportion to its visual power than red light, and was, therefore, proper for dark-room use. Certainly red light was the less actinic, but then it was so much less luminous than yellow that, when sufficient of it was employed to get luminosity by which to work equal to the yellow, there was more effect upon the sensitive salts than with a sufficient amount of yellow light. He had tried canary medium, and found it safer either than one thickness of cherry fabric or of ruby glass flashed on orange pot, and was, of course, a more pleasant and less injurious colour with which to work. The objection to it was that it was not even in thickness, and, of necessity, its safety was only equal to its thinnest places. Moreover, there was a great body of substance in the paper stopping light of all kinds, so that it was not practicable to use several thicknesses. He certainly preferred to use several folds of paper of a finer make, and to supplement these with a sheet of yellowish-green glass. Mr. Cowan had shown at a previous meeting the light obtained with this combination, and had told them that with a rapid commercial plate held close to the lantern no effect was produced with an exposure of fifteen minutes—a result, he believed, that had not hitherto been obtained with any arrangement giving good illumination.

Mr. Henderson said that there was a great difference in the speed as shown in the camera, for plates prepared by different methods gave the same number on the sensitometer. He believed that an emulsion prepared by the ammonia method, giving 16 on the sensitometer, would be as fast in the camera as one prepared by boiling and giving 20. To put this to the test he had arranged with Mr. J. Cadett (who was present) to prepare emulsions, one each way, and try them. He knew that Mr. Debenham stated that those divergences between camera and sensitometer speeds were caused by pre-exposure to light, but he (Mr. Henderson) thought they were also due to different methods of preparation. He would like to hear from their visitor, Mr. J. M. Turnbull, of Edinburgh, his experience of emulsion making.

Mr. Debenham replied that, although both Mr. W. K. Burton and himself had shown the great effect which exposure to light had in making plates give a higher number in the sensitometer than their camera speed warranted, yet he had stated that other causes might produce a similar effect, particularly any cause which would induce a weak, unsatisfactory character of image, and that the emulsion which gave the ripest and best image in the camera might not be expected to give so high a sensitometer number as one requiring the same exposure in the camera, but giving an image of inferior character.

Mr. Turnbull had given over plate making, but he had never thought so much of ammonia-prepared emulsion as of that obtained by cooking. As to the best medium for the dark-room window: in Edinburgh orange paper was generally preferred; they had not succeeded so well with yellow.

Mr. Debenham inquired whether those Edinburgh photographers who had tried yellow paper had done so with the addition of green glass.

Mr. Turnbull said that they had not. Mr. Tunny had been promised a pattern by a friend, but the sending of it had been delayed.

Mr. Debenham remarked that he had that morning received a letter from a photographer in Edinburgh, to whom he had forwarded a pattern of the glass and paper that he used. The gentleman in question said that, using it in the combination advised, he had developed rapid commercial plates in a bright light with no sign of fog, and he believed that in future he should be better able to turn out good negatives.

The opinion of the meeting was asked whether the use of sulphite of soda did or did not to any extent destroy the half-tones of the negative, as recently stated.

The Chairman found that it did.

Mr. Coles said that, when the use of sulphite of soda in the developer was introduced by Mr. Herbert B. Berkeley, Mr. G. Watmough Webster had not published his discovery of the slowing effect upon the plate of the addition of citrate of soda to the developer. It was advised to neutralise the excess of alkali in the sulphite with citric acid. This introduced an amount of citrate of soda into the developer, and had a slowing effect. If the sulphite were neutralised in the first instance with sulphurous acid, or were used without neutralising, he did not find any slowing effect, either in the time of exposure or in the development. If the plate was thinly coated there was the disadvantage that the negative was of a colour giving less printing density, but there was the great advantage that it prevented staining of the hands.

Mr. F. W. Hart had recently been exposing trial plates, and from the exposure which had been found sufficient (three seconds on a sunlit house with stop $\frac{f}{8}$) he did not think that the sulphite of potassium which the developer contained, or the citric acid which had been added to neutralise the very alkaline sample of sulphite, had had any slowing effect.

It was inquired whether Mr. Hart had made any comparative experiments with other plates at the same time developed in the usual way.

Mr. Hart had not done so.

Mr. Henderson said that some time ago he had made some emulsion for precipitation, and then had added sulphuric acid to decompose the gelatine and enable it to be entirely cleared away. The emulsion proved to be slow but very clear. The clearness was no doubt owing to the gelatine being completely eliminated. Another plan was to add pepsine, so that the gelatine might be got rid of by digestion. There was a commercial solution known as lactopeptine which he would advise to be tried.

Mr. A. Haddon inquired whether the use of sulphite of soda was attributable to Mr. Berkeley or to some other person. Mr. S. Fry, in The British Journal Photographic Almanac, had claimed for himself the credit of the general use of the article; but the particular details which he insisted upon could not be called even a modification of the methods previously published.

Mr. Turnbull said that sulphite of soda varied considerably. The proper method was certainly to neutralise with sulphurous acid.

Mr. F. York suggested that the best plan was to use sulphurous acid for neutralising, and then to filter through marble; any trace of excess of acid would then be removed.

The Chairman inquired whether any member had tried castor-oil as a vehicle for emulsification. He had done so, and had coated plates which, not being yet dry, he could not report upon, but would do so at the next meeting.

Mr. Turnbull showed a carrier for lantern slides, made upon the plan described by Mr. G. D. Macdougald, but partly of metal, so that it was thin enough to go into any lantern.

Mr. Debenham suggested that a spring should be adjusted to the frame so that it would work sidewise, instead of having to depend upon the weight of the slides. Many lanterns were only made with a side opening, and with some of the sciopticon kind it was not practicable to alter this.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

The above Association met on the 1st instant, when the President, Professor H. W. Vogel, occupied the chair. Two new members having been admitted, the Chairman placed the current photographic publications on the table. Amongst them were a Portuguese Journal—*A Arte Photographica*, and the *Annuaire pour 1884*, published by the *Bureau des Longitudes*, Paris, containing a photograph of the eclipse of the sun of 6th May, 1883, taken by Professor Janssen, Director of the Observatory at Meudon. In this photograph the corona is particularly well represented.

Herr Grimm, of Offenburg, forwarded a number of instantaneous pictures of animals.

Herr FISCHER recounted his way of testing the suitability of lenses for taking groups, particularly for ascertaining whether they give a sufficiently-good definition of a wide angle. The persons to compose a living group not always being available, he arranges a number of large letters as if they were persons, and exposes a plate.

Professor ROESE, heliographer to the Imperial Printing Establishment, showed a great number of excellent heliographs, which were formerly used in the Military Geographical Institute at Vienna.

Some dark slides used in 1870 by Herr Striedeberg were also exhibited, and proved to be similar to Herr Martini's pasteboard slides. It was, however, remarked that the priority of publication was usually supposed to be a proof of priority of invention.

Herr BIEGNER showed a wire-curtain stretcher—that is to say, an arrangement for the horizontal expansion of the curtains of a studio.

Herr GAEDIKE exhibited some dry plates of his own manufacture to which he tries to impart, as much as possible, the character of collodion plates.

Herren Haberland, Sellin, and Schultz-Hencke, who had tested some of them, pronounced them about twice as sensitive as Monckhoven's; but Herr Haberland found that they were apt to slip from the plate—a fault which might perhaps be remedied by a substratum.

Herr Frisch forwarded to the Association five of his splendid coloured lichtdruck reproductions of water-colour and pastel drawings, of which mention was made at the previous meeting of the Association.

It was resolved to hold the winter festival of the Association on Friday, the 28th March, and that ladies should be excluded.

The question-box was then opened and found to contain four questions, two of which were:—1. Is it useful or advisable to evaporate the positive silver bath and then to melt it down again? The reply was that the general experience showed that such procedure actually effected a radical restoration of the silver bath; but the Chairman considered it necessary only in the most extreme cases. He preferred to free the bath from organic substances by means of permanganate of potash. Herren Halwas and Biegner doubted that permanganate of potash could completely replace the evaporation and re-smelting, especially if the paper gave off much organic matter.—2. Is gold salt (chloride of gold and sodium) a chemical compound or only a mixture? In reply the Chairman explained that pure chloride of gold and sodium is a chemical compound, but the commercial article occasionally contained in addition an admixture of chloride of sodium.

The proceedings were brought to an end by Herr MOHR telling the following ridiculous tale:—Last year there was an international photographic exhibition at Görlitz at which a certain Herr ——, photographer at L——, received a bronze medal, of which he appears to have been somewhat proud. It occurred to some rivals in trade, who were jealous of this distinction, to doubt the existence of an exhibition at Görlitz, and accordingly they addressed an inquiry to the burgomeister of that town. He being unfortunately absent his *locum tenens* replied that there *had been no photographic exhibition at Görlitz*. Our friend's medal was thereupon regarded as a swindle, until at length by dint of sending some Görlitz newspapers containing an account of the exhibition he convinced the real magistrate of the actuality of the exhibition, and this induced him to confirm the award. The honour of the possessor of the medal was thus vindicated beyond dispute.

PHOTOGRAPHIC SOCIETY OF VIENNA.

THE above Society met on the 15th January, when the chair was taken by the President, Dr. Hornig. Several new members were admitted.

The CHAIRMAN referred in suitable terms to the death of Mr. Dallmeyer. He announced that the silver medal for progress had been awarded to Dr. Eder by the Photographic Society of Great Britain; that Herren Angerer and Göschl had received from the Emperor of Austria a gold medal in recognition of their services during the late exhibition of graphic art; and that the Société Française de Photographie had sent 100f. and M. Davanne 20f. as contributions to the Martin memorial. Further: that having considered the invitation of the Photographic Society of Berlin that the Vienna Society should take part in an international German photographic exhibition to be held at Berlin, the committee had resolved to send a collection of historically-interesting pictures and, perhaps, some sheets explanatory of new processes, on the express condition that should there be a competition for prizes at the exhibition the exhibits of the Vienna Society should be considered *hors de concours*.

The prize committee was then re-elected. It consists of Herren Angerer, Burger, Löwy, Von Melingo, Dr. Eder, and Professor Luckhardt. The committee resolved to renew the offer of all the prizes offered for competition last year for the current year except that for a monograph upon pyroxyline and collodion, and to add two new prizes, namely—1, for a dry process with collodion emulsion which should combine certainty of working and permanency with at least the sensitiveness of the wet process; and 2, for a process by which gelatine negatives may be securely and certainly drawn off the glass plate.

The CHAIRMAN called attention to some landscapes in Finland, by Herr Von Wischnakoff, portraits by Herr Solowieff, and an album full of portrait studies by Herr Schapiro, amongst which were several portraits of Herr A. Burlack, the actor, in the character of a madman.

Herr SCHLOTTERHOSS, an engineer, demonstrated an automatic exposing apparatus, and Herr JUST showed a great number of platinotype prints and prints upon emulsion paper produced by it. The apparatus may be driven by hand and separated from the electric motor. The electric part of the apparatus is said to require no special skill to manage, nor to be easily put out of order, resembling in the last respect the switching apparatus on the railway, which continues to act notwithstanding the vibration caused by the frequent passing trains.

The scrutineers who had been examining the voting papers announced the names of the office-bearers for the year, viz.:—*President:* Dr. Hornig.—*Secretary:* Herr Luckhardt.—*Treasurer:* Herr Schrank.—*Committee:* Baron Schwarz-Senborn, Graf Wimpfen, Dr. Eder, Dr. Székely, Major Volkmer, Captain Tóth, Herren Angerer, Antoine, Haack, Kramer, Löwy, and V. Melingo.

A number of articles were placed on the table for inspection—amongst others a copy of the sixth part of Dr. Eder's exhaustive *Handbook of Photography*.

The question-box was opened and, after its contents being attended to, the meeting was adjourned.

Correspondence.

A CONVENIENT SENSITOMETER.

To the EDITORS.

GENTLEMEN,—As those who make their own gelatine plates are now busy, or soon will be, perhaps the enclosed description of a sensitometer I have used for some time may, on that account, be found acceptable. This one differs from that I previously described in your pages, as with the present one two plates can be tested side by side for comparison.

On a glass plate (I use $7\frac{1}{4} \times 5\frac{1}{4}$) lay two thicknesses of pink tissue paper, and gum round the edges. This gives No. 1. For No. 2 take another double piece, only half-an-inch narrower, and gum as before; and so on, half-an-inch less for each of the remaining numbers. Number 8 will have sixteen and No. 10 twenty thicknesses.

After all the tissue paper is made secure, place another glass, $7\frac{1}{4} \times 5\frac{1}{4}$, on the top, and with gummed strips round the edges bind the two glasses together, with the pink paper between them. Then cut out of dark paper two sets of numerals and gum on, with a dividing strip across the centre of the plate.

To use this sensitometer: place the plates to be tested, face downwards, on to the numbers. Now place dark felt on the plates, screw down firmly in a pressure-frame, and expose at a distance of one foot from a paraffine candle (6 to the lb.) for one minute. Then develope with two grains of pyro. to the ounce and two drops to the ounce of—

Amm. *fort.*	1 ounce.
Brom. of potass	60 grains.
Water	3 ounces.

Let this act for three minutes and a-half (I use a sand glass) and then fix. The last number that is plain gives the sensitiveness of the plate. I find Nos 4 and 5 very suitable for ordinary landscapes, and Nos. 7 and 8 for instantaneous work.—I am, yours, &c., J. C. STENNING.

Beckenham, February, 26, 1884.

GELATINE-PAPER AS A SUBSTITUTE FOR GLASS.—TONING AND FIXING IN ONE BATH.

To the EDITORS.

GENTLEMEN,—I note your remark upon the use of gelatine-prepared paper as a substitute for glass. In a paper read by me before the Liverpool Amateur Photographic Association, some nine years ago, this transfer paper was recommended for this purpose, and negatives shown. The difficulty was, in transferring the whole of the negative to glass, to avoid the grain of the paper in printing.

As regards toning and printing in one operation: I may say that warm and pleasing tones may be procured by directly steeping the unwashed prints in a five-ounces-to-the-pint solution of hypo., to which gold has been added in the usual quantity, viz., one grain for each sheet. Immersion for ten to fifteen minutes suffices.

I do not advocate this method, but time may be saved by using it. Why do you recommend so strong a solution?—I am, yours, &c.,

Liverpool, February, 25, 1884. J. H. T. ELLERBECK.

HALATION.

To the EDITORS.

GENTLEMEN,—Allow me to point out to you that I did not feel aggrieved at space not being found for my remarks upon *Halation*, neither did I say so. I only wished to know through your "Answers to Correspondents" if my communication had reached you; hence my remarks at the meeting of the Dundee Society.

I lay no claim to be an ardent investigator, nor have I any desire to "rush" my ideas into print whether right or wrong. I simply thought I had found a means of curing halation, and I wished to give co-workers in the profession the benefit of my cure.

Am I then to infer from your remarks that the blackened cardboard does no good? Am I to believe that light does not penetrate through the gelatino-bromide film on to the back of the dark slide, and react again upon the prepared film? I may be misled in my ideas regarding what halation is, and you may call this reaction upon the back of the plate anything you like; but it is *this* (halation or not) that I hold the blackened cardboard pressed behind the plate cures, and of which I have ample proof in our everyday work.—I am, yours, &c., J. GEDDES.

Arbroath, February 25, 1884.

TONING AND FIXING BY ONE OPERATION.

To the EDITORS.

GENTLEMEN,—Referring to your article in the last number of the Journal—*The Practicability of Toning and Fixing in One Operation*—I have evidence before me in my office of the superiority of the old system of gold and hypo.

(in combination) toning over the present method, styled "alkaline toning." I have some large silver prints, 24 × 18, made by myself thirty-two years ago, toned and fixed in the one operation, that are nearly as good as on the day they were made. One thing, however, which I consider has had to do with their permanency is that plain salted, instead of albumenised, paper was used, and for large pictures plain paper has a better effect.

The washing of these prints was completed in ten minutes, thus proving, as I have contended many times with my photographic friends, the needlessness of long washing—in fact, that long washing or soaking of the prints does more harm than good. With a proper system of washing I am certain all traces of hypo. may be thoroughly removed in the time stated. I shall be pleased to show these prints to anyone favouring me with a call.—I am, yours, &c., JOHN J. ATKINSON.

37, *Manchester-street, Liverpool, February* 25, 1884.

LANTERN SLIDES IN AMERICA.

To the EDITORS.

GENTLEMEN,—When I was engaged in the United States of America as operator part of my duties consisted in making lantern slides for a well-known dealer. I have, therefore, read the letters of Mr. Hicks and Mr. Taylor with some degree of interest.

Over a period of ten months I have very often had numbers of London-made slides placed in my hands with instructions to reproduce them in *facsimile*, and I have reason to know that my reproductions were sold as "imported" slides. Certainly, in a catalogue I send herewith, they will be found quoted at a dollar and a-quarter—the retail price, in Philadelphia, of imported slides.

I have always considered it a great error of judgment that such high prices are charged by the American dealers in slides and lantern appliances in general, as it serves to deter people from purchasing. There is no doubt whatever in my mind that the prices might be reduced by more than one-half, and still leave a very large profit to the seller. During the time I was operating in Philadelphia I had sent out to me from London a few dozen English-made lantern slides of the finest quality; and previous to my returning here I was able, after having defrayed all costs of custom-house duties and freight, to dispose of them all at fifty cents each as against the dollar and a-quarter of the stores, and still make what in most lines of business would be considered a very handsome profit indeed. I need scarcely say that they were originally purchased on wholesale terms.

The excuse pleaded for charging such extremely high prices as those you find quoted in the catalogue is the comparatively small demand that exists for lantern pictures. I feel certain, however, that if the charges were approximated to those in England, or even reduced to within fifty per cent. of them, it would create a greatly-increased demand, and thus prove eventually beneficial to all concerned.

I am glad to learn that there is a prospect of a lantern business being established in the United States in which English prices are to be charged. It *can* be done, and after a short time will be found to pay well.—I am, yours, &c., ANGLO-AMERICAN OPERATOR.

London, February 26, 1884.

Notes and Queries.

I AM at a loss to know how to deal with unmounted photographs (views) to get them to remain perfectly flat, and with a polish on, like the views offered for sale, such as Frith's, Bedford's, &c. Any information will be thankfully received.—INQUIRER.

ARE there any patent rights connected with photo-mechanical printing processes in this country? If so, what are they? Has the Albertype patent expired? Is there any patent in force that would prohibit one from printing in printers' ink from gelatine films?—J. CAMERON.——In reply: There is no patent restriction on the employment of the Albert process in this country.

IN looking through the few negatives I have taken during the past season, I notice that the least unsatisfactory of them were exposed on a cloudy day or in very weak sunlight. Nearly, if not quite, all those taken in strong sunlight are hard, harsh, and unpleasing, and this defect is noticeable both in under- and over-exposed plates. I enclose for your inspection some rough trial prints I have taken from four plates selected at random. The points on which I should be glad to have your advice are—1. Whether it is desirable, in working with a lens like the portable symmetrical, to select bright, sunny days for landscapes.—2. Whether the use of a sky-shade on the lens, when working in bright sunlight, would tend to give softness to the negative.—3. Whether it is not preferable to use with the full aperture of the lens rather a small stop when a soft, delicate negative is desired.—S. CASBOURNE.——In reply: The least successful of the prints enclosed is so in consequence of a want of detail throughout, the shadows being exceptionally black. This would have been palliated, if not remedied, by modifying the developer so as to avoid intensity. Our correspondent merely requires a little more experience. The only precaution necessary in working with the lens mentioned, or indeed with any lens, is to see that no sunlight is permitted to fall upon it. The use of a sky-shade, although advantageous in some instances, is not of so much consequence for general work that it cannot be discarded. Softness and delicacy may be secured when employing a small stop, but the time of exposure must be increased. Under-exposure—no matter whether a large or small stop be made use of—invariably causes hardness, or a too-violent contrast between the lights and shadows, with an absence of detail.

IN your article on *The Use of Sulphite of Soda*, in the Journal of the 22nd instant, you give an instance of the difficulty experienced in obtaining certain chemicals. I have experienced such difficulty frequently. I have tried in vain to get citrate of ammonia and citrate of soda in Bristol within the last month. Would it be out of place to suggest that when a "rare or little-used preparation" is brought before the notice of your readers the place where it can be obtained, as well as the price, should be stated? Unfortunately, I presume, the great majority of photographers are not practical chemists, and therefore cannot make the preparations themselves.—A. L. M.——In reply: Without touching the main question as to the desirableness of indicating the places at which may be procured chemicals that are not as yet in general demand, we may state that, while sulphite of soda can now be obtained from most of the dealers in photographic materials, this may not apply to the citrates mentioned. Fortunately, these may be made very easily. In the one case liquor ammonia, and in the other bicarbonate of soda in solution, have a solution of citric acid slowly added until effervescence just ceases and neutrality is reached. The resulting solution is one of the citrate of whichever base was employed, and, if preferred, it may be evaporated to dryness.

A. B. says:—"I do not clearly understand the relationship of width of angle to focal length of single combination landscape lenses. Is it reasonable to write to an optician for a lens one inch and a-half in diameter, of a focal length of eleven inches, to cover but just so much more than a half-plate as to give fairly-straight architectural lines up to the edges of a half-plate, with an angle of not more than forty-five degrees—preferably forty? And what advantage is there with three lenses cemented together in the single combination?"——In reply: Any optician will construct a lens of the diameter and focus mentioned; but to make a single combination that will give "fairly-straight architectural lines" under the circumstances mentioned is beyond the power of any optician, unless we adopt a very elastic meaning of the term "fairly." If the word be taken in a sort of poetical sense, and is held to be synonymous with "tolerably," "moderately," or "half-and-half," then the lens will answer the purpose, provided the diaphragm is placed close to the lens (in which position the marginal definition will not be good); but if, on the other hand, "fairly" be held to be a synonym of "perfectly" or "absolutely," it cannot be done. The curvature of the lines commences at either side of the centre of the picture, but only becomes noticeable at a distance from the centre. The extent at which this is noticeable depends entirely upon the education of the eye of the observer. The advantage of three lenses over two in a single combination consists in the flint glass (which, being soft, is liable to become scratched or damaged) being protected on both sides by the harder crown glass.

"C. P." asks in last week's Journal whether varnishing a print with collodion affects its permanence. While there is no chemical reason apparent why it should do so, I have a strong suspicion that fading has been the direct result of collodion having been applied to some prints which were thus treated by me some years ago, when there was a craze, happily short-lived, for collodionising prints. The fact of the discontinuance of the practice is a strong argument against its value.—OLD PHOTO.

I HAVE had something to do with the taking of portraits at night by artificial light, and beg to inform "Night-Light" that the cheapest, best, and most easily-worked lamp is a common shallow tin saucer. It must be supplied with fuel composed of the pyrotechnic compound known as "signal fire" or "Bengal light," which is composed of sulphur, nitrate of potash, and sulphide of antimony. Placed immediately behind the saucer must be a large reflector, the best for this purpose being concave surface glass, silvered behind and protected with tin. The lantern in which the signal fire is ignited must be of very large dimensions (especially as regards the area of its front), and it must be glazed with roughly ground glass—the ground to the outside.—J. B.

LIME-LIGHT ACCIDENT.—An explosion, which shook buildings for several hundred yards distant, occurred on Friday night last, at Chadderton Town Hall, Oldham. A series of dissolving views were being exhibited, and whilst five hundred children were singing "Shall we Gather at the River?" a loud report was heard, accompanied by the smashing of windows. The room was placed in darkness. On the gas being lighted, the magic-lantern apparatus and furniture were found smashed to fragments. Children rushed down the staircase, and the police assisted numbers of them through windows and down ladders. Several were crushed; but the principal injuries were attributed to the inhalation of poisonous gas. A boy, six years of age, was suffocated, and nine others were rendered unconscious. The explosion is said to have been caused by the gas bag coming into contact with the flame. The floor of the hall was ripped up, and the room beneath—where the Chadderton Local Board assemble—was wrecked. Mr. Diggle, the photographer who was exhibiting the magic-lantern, was cut about the face and thrown down by the force of the explosion. As the gas was extinguished by the explosion, an appalling scene ensued, which was heightened by the cries of parents outside. The body of the boy who was killed was found on the staircase, he having evidently been suffocated by the pressure of the crowd. The main egress, however, was good. We learn from a correspondent that the light used was not the oxyhydrogen, as commonly supposed, but the ethoxo-lime light. In an article on this subject by the Rev. T. F. Hardwich in our ALMANAC for 1883 (page 46) he dwells at some length on the precautions necessary to make the ethoxo lime light *safe* as well as effective.

Exchange Column.

Wanted, good studio camera (whole-plate, swing-back) and stand for same. See advertisement.—Address, A. J. Brown and Son, Halstead, Essex.

I will exchange a half-plate lens, stand, and camera. Wanted, scientific apparatus or offers.—Address, A. Chambers, 8, Gordon-road, West-hill, Hastings.

I will exchange Entrekin's cabinet burnisher, in good condition, cost £5, for good interior or exterior backgrounds.—Address, E. Denny and Co., 43, St. Sidwell-street, Exeter.

I will exchange a dark tent for backgrounds (outdoor), and posing-chair with two or more backs; cash adjustment.—Address, Horace Rutley, 18, Fransfield-grove, Sydenham, S.E.

I will exchange a rolling-press, steel plate, which will take cabinets, or a conservatory background, by Marion, for a plain background in good condition.—Address, Photo., Wesley-square, Pembroke.

I will exchange Seavey's seascape background for Shew's eclipse instantaneous shutter, suitable for a whole-plate rapid symmetrical lens.—Address, S., photographer, 9, Berkeley-vale, Falmouth.

What offers for dark box, quarter-plate camera and good lens, dipping-bath, &c.; also rustic chair, imitation old stone arch, and rustic cottage window?—Address, W. H. Redshaw, Bourne, Lincolnshire.

I will give either large musical box, amateur lathe, sewing-machine, or other good exchange, for a modern tourist half-plate camera and wide-angle view lens.—Address, Beck, Belbroughton, Stourbridge.

I will exchange a cabinet burnisher, in good order, and a cabinet lens (portrait), for a universal camera, cabinet or *carte*.—Address, G. Robinson, 1, St. Mary-place, Castlegate, Berwick-on-Tweed.

I will exchange Solomon's cabinet hot rolling-press, cost £4 10s., with lamp, silver plated rollers and bed, for a good, short-focus portrait lens, cabinet or *carte*.—Address, David M. Linley, Harriet-street, Cross Louis-street, Chapeltown-road, Leeds.

I will exchange a view lens, by Lancaster, for 5 × 4 plates, to which has been added a rack and pinion, also extra small stop, as good as new. Wanted, a single meniscus for half-plates. Will give part cash for a good lens.—Address, H. Walker, 18, Yonge-park, London, N.

I will exchange the *National Encyclopædia*, thirteen volumes, perfect and as good as new, cost £7 16s.—also *Josephus' Works*, nicely bound in one volume, good as new, cost £2 11s. 6d., full of plates—for photographic apparatus. Difference adjusted in cash.—Address, B. Egginton, Tudhoe Grange Market-place, Spennymoor.

I will exchange Ross's quick-acting *carte* lens, good as new, quarter-plate mahogany sliding camera, with one dark slide, nearly new, whole-plate vulcanite bath and dipper, air-tight, and posing-chair. Wanted, a half-plate bellows-body camera and good French or other portrait lens, and quarter-plate square bellows-body camera, with three or more slides, must be in good condition, for positive work.—Address, Sulphite, 52, Goldsmith-road, Peckham, London, S.E.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

Photograph Registered.—

William Charles Waldron, Holyrood-street, Chard. — *Photograph of Charles Isaac Elton, Esq., M.P. for West Somerset.*

A. W. K.—See reply to "Amateur" in last week's issue.

Cox Brothers.—Your letter has been forwarded on as requested.

H. J. C.—The exposures will be the same, provided the lenses are identical in form and made of similar glass.

M. W. B. Collyer.—You will find an article on the subject on page 160 of our Almanac for 1881. That will give you full information.

William Surtees.—The lectures will be published in full in the *Journal of the Society of Arts;* but we believe they will not appear for several months yet.

A. R. W.—No one has yet discovered the means of taking photographs in natural colours, notwithstanding it has often been asserted in the newspapers that the thing had been accomplished.

Robt. Macfarlane, Jun.—The conditions are—employ the maximum of bromide and the minimum of gelatine. From your description of the behaviour of the plates during development we imagine they have been exposed to some injurious fumes, thus producing the veiling.

Jas. K. O'Connor.—1. The plan is not very extensively employed. The drawback to the use of the bichromate of potash is that if all the salt be not entirely eliminated the emulsion will prove very slow.—2. Not generally used. Alum is much preferred for the purpose.

E. Beveridge.—Neither of the lenses will answer quite so well as a lens specially constructed for the purpose; nevertheless, if you are content to employ a small stop they will prove very serviceable. A very small stop will be required for the smaller of the two lenses.

H. Bratt.—If you have compounded the matt varnish according to the formula we cannot understand why it should dry with a glossy surface. Of course you have not warmed the plate before applying it? If you have, that will account for the appearance you obtain.

Wm. Lang.—We have no further information than that given by the writer of the article. The gelatine you have been using is unsuitable for making Woodburytype reliefs. You require a more soluble kind. Full directions are given in the series of articles now appearing on the stannotype process; why not follow them?

A Lover of Enlargements.—By monohydrated nitric acid is meant that represented by HNO_3, and is the strongest nitric acid of commerce. It may be obtained of such firms as Messrs. Hopkin and Williams. With care there is no particular danger in making nitro-glucose. You will have to keep the temperature low, and employ strong acids. We have no idea of the value of the work in question.

Kenric B. Murray.—So many articles have appeared in the back volumes there is really nothing more to be said on the subject. There have been no improvements made beyond what have from time to time been given in our columns. Any builder will construct a studio for you, but you will have to furnish him with the design. We are not aware of a builder who makes a speciality of constructing photographic studios.

E. Y.—The cause of spots such as those in your negatives has often been explained in this column. It is that the hyposulphite of soda is not thoroughly eliminated from the gelatine; consequently the silver paper has stained the film through the varnish. No varnish will prevent staining if hypo. be left in the film. If you require further information on your previous query we shall be happy to give it if you put it in a definite form.

Beta.—It is impossible for us to judge of the quality of the lens, inasmuch as you do not state its focal length. A $\frac{f}{8}$ stop may be a very large one in the case of a short focus lens; but the same-sized stop and a long focus lens may be a very small one. The group appears to be moderately sharp. The landscape is doubled in the printing, so of the sharpness of that we can form no opinion. By employing a smaller stop a larger plate can be covered, consequently a larger angle is included. We do not agree with the writer in question.

Received.—A. C. Doyle, M.B., C.M.; W. H. Harrison. Thanks.

Photographic Club.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, March 5th, the subject for discussion will be—*On the Advantages or Disadvantages of Sulphite of Soda in the Developer.*

South London Photographic Society.—The next meeting of this Society will be held in the Rooms of the Society of Arts, John-street, Adelphi, W.C., on Thursday next, March 6th, at eight o'clock, when the adjourned discussion on *Whether Pictures upon Ready-Sensitised Paper are More or Less Likely to be Permanent than those on Ordinary Paper*, will be resumed, and Mr. Edward Dunmore will read a paper upon *Old Photographs*. Members and friends having old photographs (of the method of production of which they can give particulars) will oblige by exhibiting them.

The Postal Photographic Society.—Mr. H. H. Cunningham, B.A., who has acted as Hon. Secretary to this Society since its formation in 1882, has been offered by the Earl of Derby, and has accepted, the appointment of stipendiary magistrate in British Guiana. Mr. Cunningham has, therefore, been compelled to resign his post as Hon. Secretary, and it is requested that, till the appointment of his successor, all communications be addressed to the Hon. Treasurer, Mr. W. M. Baylis, 3. Plowden Buildings, Temple, E.C.

The Tricyclists' Camera Stand.—Among the pieces of apparatus which were especially noticeable at the late exhibition of the Photographic Society of Great Britain was a camera stand that, when erected, was of the usual height and possessed a remarkable degree of rigidity, especially when its unusual lightness was taken into consideration. Its leading "idea," however, consisted in the ease with which it could be packed in any portmanteau of twenty inches in length, this being the longitudinal dimensions of the stand in question. Messrs. J. F. Shew and Co., the manufacturers of the stand, have just issued what may be termed a new or tricyclists' "edition" of it, in which certain features of advantage find place. The most noteworthy of these is the mechanism effecting the junction of the legs with the top, all loose screws being now done away with. This renders it useful to the tourist. There is also a combination of the keyhole and bayonet joint which, as applied to the joints found in this stand, confers rigidity in use and comfort in erecting it. The extent to which the legs are capable of being elongated or shortened to suit inequalities in the ground is no less than twenty inches, which forms the length of the three sets of elementary portions of which this portmanteau or tricycle stand is composed. Including the top, together with all the bolts and nuts, the weight of the stand is only two pounds nine ounces, which, with its other good features, must render this stand a boon conferred on tricyclists, or travellers who desire their *impedimenta* stored away in the recesses of a small portmanteau.

POLARISED LIGHT.

All who witnessed the brilliant demonstrations of the effects of polarised light, given by Messrs. Darker Brothers, at the last meeting of the London and Provincial Photographic Association, must have felt astonishment at their extraordinary nature, as well as gratification and pleasure in seeing objects which were intrinsically beautiful, in addition to being interesting and instructive from a scientific point of view. Messrs. Darker have for many years been recognised as authorities in all that appertains to the polarisation of light, whether as regards the manufacturing of the special appliances for conducting this line of demonstration and experiment, the possession of specimens of polariscope objects which in many instances are unique, the successful exhibition of them in public, or, we may add the "coaching" of popular lecturers on this imperfectly-understood subject. Their demonstration at the meeting referred to was the second of this description, being by special request, and serving as a continuation of one they gave a few weeks ago towards the termination of the ordinary business, when it came in the form of a *bonne bouche*.

The varied phenomena arising from the polarisation of light have for a long period been known, and it is not surprising that soon after the organisation of the Photographic Society, in 1853, attention was prominently directed to the advantages conferred by photography in securing permanent records of such phenomena. But we read that in the year just mentioned the light by which certain crystalline structures were eventually displayed upon the ground glass of the camera "was so exceedingly faint, having to pass through many thicknesses of glass beside two dark brown tourmalines not a quarter of an inch square, that no image could be perceived on the focussing-glass unless the camera was held pointed direct to the sun, and every other light carefully excluded from the eye:" when that is contrasted with the projection of similar objects brilliantly illuminated upon a large screen by the oxy-hydrogen polarising lantern, so as to be plainly visible by a large audience, then we realise the great progress made in this particular department of applied science.

The special lantern by which all the effects of polarisation may be exhibited to an assembly comprising numerous spectators is of a somewhat simple description, and analogous to the polarising arrangement of the microscope. First of all, the body of the lantern is not only of similar construction to that in everyday use for the projection of photographic transparencies, but the polariscope addition is in reality an attachment to this lantern. The body, the light, and the condensers are therefore required in common for both purposes.

The first departure from the usual routine of lantern pictorial projection takes place just outside of the condensers where the emergent beam of light is polarised. This is effected by interposing in the path of the light a parcel or bundle of plates of plain glass carefully selected with a view to flatness, good polish, and freedom from scratches, air-bubbles, or defects of a similar character. Thin patent plate answers the purpose better than any other kind of glass. Of these there must be from nine to eleven or twelve so packed as to lie close to each other. Nine such plates form the smallest number that can be successfully employed for the object intended. Those who are fortunate enough to possess any of the thin French glass that was employed several years ago in connection with stereoscopic transparencies will, probably, find in such glass that which is best of all suited for the purpose. A bundle of glass of this description having been interposed at an angle of 57° in the path of the emergent beam, the light becomes, by such simple means, quite polarised.

But the inquiry will here be made, "which light?" for, when placed at such an angle, a large portion will be reflected from the surface of the glass, the remainder being transmitted. To this we reply that both the light reflected and the light transmitted are polarised, and the various phenomena dependent upon such light can be shown by either; but the advantages arising from the reflected beam so greatly exceed that from transmission as to cause the former to be almost exclusively employed, and, in consequence, there is an angular bend in the tube containing the optical system of all polarising lanterns. Here again, it may be asked—"What *is* the polarisation of light? or what is the difference between ordinary light and polarised light?" The easiest mode of replying to these queries is to assume that ordinary light consists in a vibration of the etherial particles in planes resolvable into two at right angles, and that polarised light is wanting in one of those sets of vibrations. Any means by which these are separated prove to be polarisers of light, and among such means the bundle of glass plates of which we have spoken answers the purpose well.

When only small objects are to be viewed by polarised light, a Nicol prism (composed of a rhomb of calcite or Iceland spar, divided and re-cemented in such a manner as to eventually transmit only one of the images which it is the property of this crystal to show in duplicate) forms the best polariser, and this is always employed in the polariscopes fitted for use with the microscope. But no Nicol prism has yet been obtained of such large dimensions as to be practically available for application to the lantern as a polariser.

But, if not suited for such purpose, the Nicol prism is admirably adapted for effecting the part of the second element in the polariscope, namely, that of analyser. When a ray has been polarised and deprived of its vibration in one direction, it is sufficient that the ray be transmitted through such a body as the Nicol prism, which, when placed in a certain relation to the ray, obliterates it on the same principle on which the original ray was deprived of its motion. Of course, under these circumstances, darkness ensues by the horizontally-vibrating ray having been stopped by one and the vertical ray by the other of these agents in polarisation.

The various phenomena of polarisation are observed by the insertion of the body to be examined between the polariser and the analyser, and some of the effects produced are magnificent in the extreme. Simple crystalline substances that are almost invisible—such as a drop of a solution of washing soda spread upon a glass slide and allowed to become dry—display not only the most beautiful forms but the most gorgeous colours. If a piece of glass be examined, and one side then subjected to pressure, the strain thus caused upon the substance of the glass, although invisible under ordinary circumstances, is here rendered most palpably distinct by a series of black bands or lines starting from the point of pressure and extending to a distance corresponding with the degree of pressure. Incidentally, this shows that an otherwise first-class lens may have its excellence seriously impaired by being screwed or burnished too tightly into its cell. This also occurs when any piece of glass has not been properly annealed and internal strain is set up. The polariscope reveals every, even the slightest, defect of this nature.

By their appearance by polarised light the difference between two nearly similar crystals can be immediately discovered. No one who has ever witnessed in this way the difference displayed between two drops respectively of weak solutions of iodide of cadmium and bromide of cadmium would ever afterwards mistake them. In this way it acts as an analyst or detective.

We have said that in order to polarise the light properly the bundle of glass plates must be placed at an angle of 57° to the light. This angle is determined, for any substance, in accordance with Brewster's law—that when the tangent of the angle of incidence is equal to the refractive index of the medium upon which the light is incident, the reflected ray is completely polarised, its undulations taking place in one plane only. Therefore as plate glass has a refractive index of 1·54, the angle of which it is the tangent is 57°, and this is the angle at which the parcel of plates of glass must be placed when it is desired to fit up a lantern or any other instrument to investigate the subject of the polarisation of light. We hope that what we have written will prove the means of inducing many of our readers to enter into this field of physical research and recreation.

ON PHOTOGRAPHING COINS, MEDALS, &c.

It frequently happens that an apparently simple application of photography proves exceedingly difficult to carry out in practice until a certain amount of experience has been acquired in the method of working. This remark is well exemplified in the photographing of coins or medals. This, at first sight, appears a simple operation, yet those who attempt it for the first time often meet with no little difficulty. As an illustration: let us suppose that a photograph of a gold, silver, or bronze medal gained at some exhibition be required, as it frequently is, for advertising purposes. In the first place the medal has to be secured in position on a suitable background, and it is obvious that the means of attachment must not be apparent in the picture.

If the negative be required for any of the photo-mechanical processes (and, consequently, reversed), the matter is simple enough. The medal has only to be laid on a suitably-tinted piece of cardboard to form a background, and placed on the floor. Then the camera is arranged so that the prism or reversing mirror is directed downwards instead of sideways. Of course, the illumination must be so arranged that the dominant light shall fall on the medal from the side and not from the top, and at a considerable angle, otherwise there will be but little or no relief in the picture.

But, presuming the medal has to be photographed from a vertical position (this being generally the case): it must be secured in some way or other, and it frequently happens that its owner will not permit any form of cement to be employed for the purpose owing to his fear of its soiling the metal. This difficulty may be overcome thus:—Take a piece of stout mounting board of a tint suitable to form a good background. On this lay the medal, and with a pencil make a mark round the rim; then, with a sharp penknife, cut out a clean hole, keeping the knife slightly within the line. Into this hole the medal will fit tightly and be held securely. On no account must the medal be pressed in flush with the surface of the cardboard, otherwise the photograph will appear wanting in relief. In lighting the medal, some little judgment is required in order to obtain good *chiaroscuro* in the design. A good, strong side light must be employed, but not at too great an angle, otherwise the outline of the medal may become lost in the strong cast shadow from its rim.

New gold or bronze medals or coins are much easier to photograph than silver—the latter metal, when fresh from the die, often causing considerable trouble by reason of the strong reflection from the bright portions. This difficulty can, however, be avoided by dabbing the surface over with a piece of common putty; but it is seldom the owner of the medal will permit this to be done, and the operator must therefore rely upon his skill in lighting alone. A very full exposure in all cases must be given, and a well-restrained developer should be employed to bring out the image.

In most instances where a medal has to be photographed both the obverse and the reverse have to show in the same picture. When this is the case, of course two negatives must be taken. They may then be combined by one or other of the methods described in the articles which recently appeared in our columns on *Combination Printing*. Here is a plan which is sometimes adopted:—The background in each negative is blocked out, and the two negatives are then fitted together and secured to the glass of the pressure-frame, a piece of opaque paper being pasted over the junction of the two glasses. Of course by this method a white background is secured in the prints, which is often a desideratum. Frequently when medals gained at exhibitions are used for advertising purposes they are duplicated—both the obverse and the reverse—by the electrotype process; then both sides can, of course, be copied on the same negative.

Now, the photographing of a medal or coin—be it gold, silver, or bronze—while it is new and unsoiled and the design clear and sharp, is an exceedingly simple affair compared with copying ancient coins, such as those in numismatical collections. Many of these are old bronze coins—centuries old—with the design and inscription wellnigh obliterated with age and the wear to which they were subjected during the period they were in circulation as current coin. In addition to the design being nearly all worn off (so that, however skilfully the lighting may be arranged, little or no relief can be obtained in the negative), the difficulty of the photographer is often increased by the coin being oxidised in some portions, while others are bright, and therefore reflect light. The difficulty is still further increased when, as is frequently the case, a number of coins—gold, silver, and copper—have to be included in the same negative.

Yet such work is executed, and ancient coins (whether they be of gold, silver, or baser metal) are successfully represented by photography, as witness the illustrations in several works on numismatics, and also the examples which have been shown from time to time at the different photographic exhibitions. How is it accomplished? Simply enough. The negatives are not made direct from the coins at all, but from casts taken from them, either in plaster of Paris, wax, or sulphur. With either of these materials all the sharpness (be it much or little) in the original design is secured. But, for the purposes of photography, the plaster of Paris is much to be preferred, as its surface is dead and absorbent, while that of either of the others is more or less bright and reflective of light. Indeed, it is the dead surface of the plaster which enables a much sharper photograph to be taken from the cast than can possibly be obtained from the original with its reflecting metallic surface. It may be mentioned that the plaster used for this class of work is a specially-fine kind prepared expressly for modellers, and is not the ordinary plaster of Paris of the oil shops.

It will now be seen that the copying of a number of ancient coins of different metals in one negative is not such a difficult undertaking after all if this plan be adopted. No matter how oxidised, discoloured, or bright the coins themselves may be, the colour, of course, is not reproduced in the cast. Still, even with the plaster casts, some amount of skill is requisite in the illumination in order to secure a marked relief in the inscription and design, particularly if it be much worn in the original.

Matters may still be further simplified if, in making the casts, a small quantity of some dark pigment—such, for example, as burnt umber—be mixed with the plaster of Paris, as it will take off its dazzling whiteness, and enable better effects in *chiaroscuro* to be obtained. When coins of gold, silver, copper, or bronze have to be included in the same picture, the plaster used for the gold and copper ones should be more deeply tinted than for the silver, so that they appear somewhat darker in the photograph.

From the foregoing it will be seen that whenever medals or coins, even if they be new, have to be photographed, and the best results are imperative, it will in all cases be advisable, when possible, to have tinted plaster casts taken, and to photograph these. When this is done a sharper and crisper picture, and one fuller of detail, will always be secured than it is possible to obtain from the originals with their bright, reflecting surfaces.

HYGROMETERS.

At the commencement of the year we devoted an article to the subject of moisture in the atmosphere, and showed the important part it played in the everyday economy of the studio, and the bearing it had even upon the permanency of prints. We now revert to the matter with the intention of giving some practical hints as to the ready determination of the moisture at any time present in the air—a subject which cannot but be of considerable importance when we reflect how greatly it influences such processes as the drying of emulsion plates, of carbon tissue, and of mounted prints, besides the manner it operates upon the preservation of apparatus and the storage of negatives, not to speak of its more intricate connection with weather forecasting. These points of view were sufficiently treated in our article already alluded to, a passing reference to which is all that is now required.

Though a minute and scientific amount of precision is not necessary in hygrometrical observations in the studio or the workroom of the photographer, the trouble involved in making notes possessing considerable accuracy is so slight that it is desirable to bring before our readers the very simple arrangement which is largely used for such meteorological purposes at a great number of stations throughout the country. Meanwhile it may be said that indicators so slight as those found in many popular weather glasses are by no means devoid of moisture-registering power. Thus, there is often to be found in the old wheel barometer a little dial with index indicating moisture or drought which is usually actuated by an awn or small vegetable filament which, under the action of moisture, twists or untwists, and so moves the index. A human hair is very sensitive to moisture, and some time ago we called attention to an instrument intended for actual scientific use which was worked simply by the contraction and expansion of such a hair. Then, again, an instrument so primitive and unscientific looking as the old-fashioned chimney ornament, in which figures were made to enter or leave a little portico according to the amount of atmospheric humidity—such movements being caused by the expansion of catgut from moisture—gave decided indications of changes in the state of the air.

Leaving these now on one side, the reference to them indicating how readily an ingenious and handy worker could contrive an instrument possessing appreciable utility founded on the use of some hygrometric substance, we may now describe the wet and dry bulb thermometer, often termed "Mason's hygrometer."

This instrument is founded primarily on that very property of vapour which renders it so desirable for the photographer to possess a measure of its power; that is, the increase or decrease in the amount of aqueous evaporation according to the increase or decrease of moisture present at the time in the atmosphere. It is well known that evaporation involves a loss of sensible heat, or, in other words, produces cold. The quicker the evaporation the greater the cold; hence, if two similar thermometers be exposed to the air, one being in its ordinary condition and the bulb of the other kept constantly moist, it is obvious that evaporation will, usually, be continually taking place from the wet bulb, and that it will, in consequence, give a lower reading than its companion dry bulb thermometer. Increased cold following increase of evaporation—which latter condition naturally follows diminution of the amount of atmospheric moisture—it is obvious, *per contra*, that whenever there is a large amount of water in the air evaporation will be so slight that the two thermometers will show very little difference in their readings; but if the air contain little moisture, or is "dry," the difference will be considerable.

We may further remind our readers that as the utmost possible amount of water which may be contained in the air increases very considerably with increase of temperature, the difference shown by the two readings of the thermometer has to be considered in conjunction with the actual temperature when the observation is made, if a correct idea has to be formed of the evaporating power of the air. Thus, when the two thermometers read alike, the air could contain no more or would be "saturated;" neither prints nor tissue would dry, and any negative brought out of a cold room would instantly be covered with moisture. If, however, by artificial means the temperature were raised, the water present would naturally remain constant, but the moisture-containing power of the air would be vastly greater—a fact explaining one advantage gained by raising the temperature of drying-rooms.

In practice the mode adopted for keeping the bulb wet consists in tying round it a piece of thin muslin, which is kept moist by a piece of soft cotton thread—such as thin, open lamp-wick—leading from the bulb to a small reservoir of distilled or rain water kept at one side, capillary attraction serving to keep the bulb continually wet.

Such instruments are usually more costly than ordinary thermometers, but the photographer can readily make one himself. Two thermometers (common shilling instruments will answer) as nearly alike as possible, and with the freezing-points about the same distance from the bulb, should be chosen, the tubes removed from the frames, and the latter sawn off at the freezing-point. The tubes after being carefully replaced will project a little distance below their wooden support, leaving the bulbs free to be acted upon by the air. The two shortened instruments may now be mounted side by side upon a small board, which they are kept from touching by a half-inch bar of wood, to which they may be screwed. To one corner of the board may be attached a half-ounce, narrow-mouthed phial for holding the water, into which the thread from the muslin-covered bulb dips, and then the instrument is complete.

Mr. J. Glaisher, the esteemed President of the Photographic Society of Great Britain, has made a very elaborate series of investigations and calculations on this subject, and has embodied the results in a series of tables, the following abstract of which is self explanatory:—

Temperature by the Dry Bulb Thermometer.	Difference between Dry Bulb and Wet Bulb Readings.					
	2°	4°	6°	8°	10°	12°
	Degree of Humidity.					
34°	79	63	50	..	..	..
36	82	66	53	..	..	..
38	83	68	56	45	..	..
40	84	70	58	47	..	..
42	84	71	59	49	..	..
44	85	72	60	50	..	..
46	86	73	61	51	..	..
48	86	73	62	52	44	..
50	86	74	63	53	45	..
52	86	74	64	54	46	..
54	86	74	64	55	47	..
56	87	75	65	56	48	..
58	87	76	66	57	49	..
60	88	76	66	58	50	43
62	88	77	67	58	50	44
64	88	77	67	59	51	45
66	88	78	68	60	52	45
68	88	78	68	60	52	46
70	88	78	69	61	53	47
72	89	79	69	61	54	48
74	89	79	70	62	55	48
76	89	79	71	63	55	49
78	89	79	71	63	56	50
80	90	80	71	63	56	50
82	90	80	72	64	57	51
84	90	80	72	64	57	51
86	90	80	72	64	58	52

This table, it will be seen, gives the relative amount of moisture contained in the air at various temperatures for each difference of two degrees in the readings of the wet and dry bulb thermometers. It does not give the actual amount, nor the difference in amount that would be found by raising the temperature of air possessing a given amount of humidity. To do so would require either too extended a table or the use of calculations with which we do not desire to complicate the subject. With the aid of such a thermometer as we describe and the use of this table observations of considerable value may be made, and we trust that the valuable assistance which Mr. Glaisher's tables as abstracted will afford may render our remarks useful to a large circle of readers.

It will be remembered that at the time the new Patent Act was passed we called the special attention of photographers to one of its clauses, namely, that which prohibits the use of the Royal Arms for any purpose whatever, without legal authority, under a penalty of £20. In reference to this subject the Board of Green Cloth has given notice that, by section 106 of the Patents, Designs, and Trade Marks Act of 1883, a penalty of £20 is incurred by any person who, without proper authority, shall assume the Royal Arms with a view to lead other persons to believe that they are employed under any department of the Royal Household. This monition is promulgated by order of the Lord Steward, Lord Sydney.

The *Athenæum* gives prominence to the suggestion of a correspondent that photographic and other artists will not suffer to vanish and leave no record of the quaint mouldings and jutting storeys of the picturesque old house near the St. Clement's end of Wych-street, now in course of demolition. We cannot better serve the desire expressed than to call attention to it in these columns. The same paragraph states that there are two good views of the house extant, the Society for Photographing Relics of Old London having published them in 1876.

We extract from a trade journal the following information:—"Those who practise the bichromate process of photography must of necessity get the skin stained by this chemical, which produces a reddish-brown stain that is not thoroughly removed by washing with soap and water. If, however, a small quantity of sulphuric acid be added to a strong solution of hyposulphite of soda, and applied to the skin, the stain can be quickly removed; or the same effect can be obtained by the use of a little sulphurous acid, and afterwards washing in rain or distilled water." We should like to be informed what or which "the bichromate process of photography" means.

The water analysts have been taking a leaf out of the photographer's book, Dr. A. R. Leeds having, in a preliminary and as yet unpublished note to the New York Academy of Sciences, called attention to a new actinic method for determining putrescible organic matter in potable waters. A certain amount of the water under examination is mixed with a measured quantity of nitrate of silver solution, and the mixture exposed to light after the old method of sunning the bath. The organic matter becomes oxidised and the silver reduced to the metallic state, when it precipitates or adheres to the sides of the bottle. This silver is washed, collected, redissolved in nitric acid, and estimated. From its weight the amount of oxygen used up to oxidise the putrescent matter can easily be calculated. Mr. Nelson H. Darton, of New York, states that so far the process has yielded most satisfactory results, and promises to be a "convenient, applicable, and accurate method for the analysis of potable waters."

In writing of pure water we are naturally reminded of a recent letter to *The Times*, by Dr. Frankland, in which he points out how gravely the possibilities of water purity are compromised by a recent decision of Mr. Justice Pearson (case of Ballard *v.* Tomlinson). Briefly put, the matter lies thus:—A certain brewer depended on the purity of his well water for brewing good beer, but a neighbour who had a disused well about a hundred yards away used it as a cess-pit, and the contents leaked through the strata into the brewer's well, and so ruined it for brewing purposes. The law gave him no remedy. "Hence," says Dr. Frankland, "a man may not discharge noxious matter into surface water, but may do as he likes with subterranean water." He further draws a picture of a possible aniline dye manufacturer working a factory in the neighbourhood of the deep wells used by the Kent Water Company for the water supply of a part of the metropolis, and discharging his waste arsenical liquor into the subterranean reservoir from which the water is drawn. We do not know that arsenic would injure a dry-plate film to any great extent, but it would certainly be startling to find a batch of negatives left to wash dyed red through the filtration of waste magenta into the water supply.

According to the *Lancet*, luminous paint when unprotected is found to be perceptibly blackened by the fumes from fresh lead paint in its vicinity. We have not met with any such experience ourselves, and it would be interesting to learn if this alleged fact can be substantiated by any of our readers.

It has been suggested to us by a correspondent that a large source of albumen is entirely lost sight of in failing to utilise the humours of the eyes of oxen slaughtered for food. As it is not likely that they could be had in sufficient quantity or be rendered practically available—if even they could be shown to possess suitable properties for photographic use—the suggestion must merely pass as a curiosity. The more so as, according to a continental chemist, there is very little albumenoid matter in the human eye, its viscidity being, he considers, due to an excess of salts over albumenoids.

The authorities of the Observatory at Paris seem to be in hot water just at present. They hold a large area of "eligible building sites" which, if sold, would enable another observatory to be built in a more favourably-situated spot without incurring any expense; but the plan is warmly denounced. A member of the section of astronomy said he was sure that if an astronomer wished to execute any special work for which provision did not exist at Paris M. Janssen would lend his instruments and grounds. To this M. Janssen replied that he would be most happy, as the Observatory was not his private property, but belonged to the Government.

An interesting comment upon the capability of a large reflector retaining its surface for a considerable time is made by the director of the Observatory at Melbourne with regard to the large reflector there, which has been in use for twenty years. He says the inevitable loss of reflection power in the great telescope increases a little year by year, but does not yet sensibly affect the work upon which it is employed. Indeed, Mr. Ellery remarks—"Some photographs of faint objects obtained lately are clear evidence of the immense light-gathering power it still possesses, and of the trivial loss occasioned so far by the slight tarnish apparent."

SODIC SULPHITE AND ITS CRITICS: PLATINOTYPE AND ERRONEOUS IMPRESSIONS.

Doubtless there is a very strong "case" in favour of sodic sulphite; but, while agreeing to the full in Mr. Samuel Fry's estimate of its value in the alkaline developer, I cannot follow him in his statement that the thorough, practical, value of the method is due to his recommendation to use boiling water instead of cold water for making the solution. The only real advantage in using the former in this case would be more quickly to dissolve the salt. To one in a hurry there would be an advantage, but to none other. When the solution had cooled it would be just like one made with the same quantity of cold water; and, of course, any excess of the salt, if present, would be thrown out on cooling.

I say that without doubt my formula and instructions, as originally published by me, strictly followed, are as "definite" and as good as any—better than most—that have been published since by others, and by those who seem to think there is a difference "betwixt tweedledum and tweedledee."

The whole of the advantages set forth by Mr. Fry were pointed out by me, with the exception of the suitability of the colour of the image for the retouching pencil; and I contend (as, of course, many others, including the Editors,* could testify) that the preparation as made under my supervision after that formula, and sold by the Platinotype Company, was equal to any, and better than most, of the preparations emanating from other sources. So much for the original formula.

Since advertisements are *sometimes* admitted into these columns, I may be permitted to add that I have improved upon my original method (but *not* by using "boiling water"). This modification, however, it is not my intention to publish; and, after all, is there much inducement to do so, seeing that either the solutions, being

* By-the-bye, why do the Editors allow misleading statements to be published unnoticed at the expense of their supporters and original contributors? Is it "*pour encourager les autres?*"

ill-made, obtain a bad name, or else that my rightful claim to such little credit as may attach to the matter is sought to be transferred to other names than mine?

I have thought over these and kindred matters often enough, and am firmly of opinion that the man who will not only originate, but also *carry out his ideas commercially*, putting them in the way of the public, is doing more for that public, not less than for himself, than he could possibly effect by making a "clean breast" of all he knows—virtually, in most cases, that men may try, fail, and abuse; and, perhaps, finally, in the mind's eye, catching a sight of the bantling dressed in clothes of their own making, that they may condescend to pick him up, give him a *hot bath*, and then, as an adopted child, dandle him before the admiring gaze of a gullible public.

Since writing the foregoing I have read Mr. B. J. Edwards's communication in the last number of this Journal. Well, I suppose we can all be right under certain conditions. But these do vary—especially in chemicals; and so does the manner of using the latter. For my own part, having seen a goodly number of negatives produced by almost as many operators, my experience tells me that there is much less gradation generally to be found in the negatives developed by ordinary alkaline pyro. than in those developed with such preparations containing sulphite as I have confidence in. Still, it is certain that a rather bad thing worked well may turn out better results than may a good thing used badly. A large quantity of negatives, developed by the ordinary developer, are stained in the shadows and flat and thin in the high lights; they very commonly have one or the other of these defects. Now, when sulphite has been properly used at least there is no stain, and the parts not acted upon are clean. Such a negative, if not sufficiently intense, may at least be easily intensified; while, by allowing the proper time and by not rushing the development, any amount of intensity and sparkle may be obtained. Some say that they get the same effect by using "clearing solutions;" but I do not think this is so—certainly not always. Besides, "prevention is better than cure."

Mr. Edwards makes—or is made to make—the statement that the same developer by which eight negatives were developed in succession was kept for twelve months after mixing and then used with success. Are we to understand that the *alkaline* developer was kept for twelve months after mixing, or the solution of pyrogallic acid only? I should like to know what was the colour of the developer after eight negatives had passed through the solution, or, what would be more to the point, the colour of the negatives; how long the films were subjected to the solution; and, also, the quantity of ammonia present, particularly after several of the plates had been developed.

Such a method of working—if "method" it can be called—is quite feasible with sulphite, and the developer may be kept for twelve months afterwards without further discolouration. I have now such a solution with which was developed a plate for the long period of half-an-hour. This was fully two-and-a-half years ago. It is still only straw-coloured. Such experiments, if not tending to methodic modes of working, are at least interesting. That citrate of ammonia may have a certain amount of retarding effect upon the oxidation of alkaline pyro. is extremely probable. Sulphate of ammonia has a very decided influence in this respect.

Now, of course, if Mr. Edwards admires stain in the shadows or an ochre-coloured image—just as some admire green fog—or the use of clearing-baths, it would be quite impossible to make a convert of him; but if, on the contrary, he admire what has been called "wet-plate quality," I should like him to try some sulpho-pyrogallol, as prepared by the Platinotype Company under my directions, and also to follow one or two hints which I should give him. Then let us hear again from him, and I think he will have a different tale to tell. Nevertheless, as I have said before, methods of working greatly affect success; one will succeed and another fail with most methods. Still, of this I am certain—that to most workers sulphite is of very great value; of this I have absolute proof in the shape of numerous letters.

In the same number, in an article entitled *Onward*, Mr. A. F. Genlain does me the honour to eulogise my platinotype work. Now, it is not with the object of pointing out "what a good boy am I" that these remarks are written, but to impress upon Mr. Genlain and on others who may believe that there is "a lot in understanding the process, don't you know?" that platinotype, being the simplest of printing processes, ought to be *tried*—fairly tried—before giving way to the feeling to which Mr. Genlain gives an almost fervent utterance. No; what little pictorial value there may be in my occasional efforts is not due to my "knowledge of platinotype" (though it may be partially to the method of printing—so artists say), but to the choosing, lighting, and development of the negative, combined with a few "dodges" common to silver printers.

But, *apropos* of the subject which commenced this communication, how greatly has sulphite aided in the little negative work I have done since I have adopted platinotype! Of your sickly-yellow negatives, with that density which should be piled on the extreme high lights spread over the extreme shadows, I have seen the last. But no; I am still doomed to see those held up to me by others for my admiration or approval—or condemnation!

But, really, Mr. Genlain, why despair before you have tried? Why lament when you might rejoice? But is Mr. Genlain quite in earnest? I am, and have very good reason to ask the question. In this I mean nothing personal, Mr. Genlain being entirely a stranger to me. HERBERT B. BERKELEY.

STANNOTYPE.

No. V.

BEFORE exposing the tissue it is presumed that a suitable transparency has been obtained, and that it has been properly prepared for this special purpose. The qualities desirable in the positive have already been described in a previous article, and mention has also been made of the importance which attaches to the "safe-edge." We may at this point, however, reiterate the remarks made in this latter connection.

The positive itself represents the picture to be reproduced, surrounded by a margin of practically-clear glass—the "safe-edge," in fact. In making the relief it is, of course, again necessary to form a "safe-edge" by pasting strips of opaque or semi-opaque paper along the edges of the transparency; but, in doing so, it is imperative that these strips of paper be *narrower* than those originally employed, and that they be so attached to the positive that *a line or band of clear glass be left between the picture itself and the strips of paper.* Upon this simple point the whole success of the printing operations depends. As we have pointed out, this space of clear glass represents the highest lights in the relief or printing surface, from which all the other gradations take their value. Thus, the margin of the relief is represented in the print by pure white; and if in the picture itself there be any point or points which should be perfectly white they will be as high in relief as the border, the lower tints being all in proportionately lower relief.

Now, it can be well understood why such importance is attached to the preservation of clear glass in the high lights of the transparency or positive. However perfect the positive may be in its proportionate gradations, it stands to reason that if its highest lights are not clear glass they must necessarily exhibit a certain amount of "tint" in printing, owing to the higher relief of the margin or border, and, in fact, the tone of the whole picture is degraded. A fogged or an over-developed transparency which—being perfect in its gradations—is perfectly suitable for enlarging purposes, or will even pass muster satisfactorily from an artistic point of view, is wholly unsuited to the requirements of stannotype, for the simple reason that the fog or veil is inevitably reproduced in each print, and no variation in the intensity of the printing ink or of the pressure employed will avail to prevent it.

It may be remarked, *en parenthèse*, that though the statement just made as to the inevitable reproduction of any fog or veil existing in the transparency is practically correct, a certain modification may be made. If the marginal zone of clear glass can be dulled or degraded to the same tint as the highest light in the veiled transparency, then the same effect will be produced as if high lights and safe-edge were both clear glass. But, we imagine, the skill and judgment necessary to effect such a modification of an imperfect positive would be sufficiently great to render the production of a new transparency the preferable course. However, in cases were such reproduction is an impossibility, it may be useful to know that the expenditure of some care and trouble may render an otherwise useless transparency available.

So much having been said with regard to the preparation of the positive, we come now to the actual exposure of the tissue. This presents no special difficulties or peculiarities, and differs only from the ordinary practice in carbon printing in that the tissue being thicker and less pliable requires even greater care in order to secure perfect contact with the transparency during printing than is the case with the usual "portrait" tissue. A printing-frame, with plate glass front, is almost—if not absolutely—a necessity, in order to permit the application of sufficient pressure to *ensure* perfect contact. In practice, if the tissue have been properly kept and in a flat state before use, the difficulties will not be great—not so great, in fact, as with ordinary tissue—but, in order to be "on the safe side," it is well to observe the direction with regard to the pressure-frame.

As regards the time of exposure, it is, of course, quite impossible to give any explicit directions, as so much depends upon the conditions of light, density of transparency, depth of colour of the tissue, and strength of sensitising bath, together with minor circumstances which may work in to modify the final result. It may, however, be taken that the exposure usually required will be from three to six times as long as for an ordinary carbon print, the time being proportionately shorter in a good light—summer sunshine—than in the dull light of winter. The so-called "continuating action"—*i.e.*, the effect which is produced by keeping the tissue for some time after exposure and before development—must also be taken into account; but in any case a photometer is a matter of necessity.

Perhaps the best for this purpose is the well-known "Woodbury" photometer which has been frequently described in these columns; but on using it for this special purpose it will be necessary to employ one or other of the coloured discs supplied with the instrument in order to bring its "tints" within the range of present circumstances. The Warnerke sensitometer scale forms a useful photometer for the purpose of gauging the exposure of the positive, and with the interposition of a sheet of coloured glass or gelatine would, no doubt, answer equally well for the longer exposure of the relief. But in any case a graduated scale for photometric purposes is easily made, and especially so by the stannotype process itself. It is, indeed, by "Woodbury" printing that the Warnerke scales are made, the relief being produced in, practically, the manner we shall describe.

On a piece of patent plate glass lay down by means of paste or other suitable mountant a piece of paper, tinfoil, or other material; on this lay in the same manner a second piece a-quarter of an inch shorter, and on this again a third also a-quarter of an inch shorter, and so on until a scale of sufficient range is formed. This being done cut neatly round the edges of the "scale" to form a clean square or oblong, and paste round this a frame composed of a number of thicknesses of the same material—paper or tinfoil—greater by one thickness than the largest number employed in the scale itself. If tinfoil be used the scale so produced is ready for employment as a printing surface. If paper be the material adopted it will be necessary to face it with tinfoil first before employing it for that purpose.

We have now a matrix from which any number of photometer or sensitometer scales can be produced by means of gelatinous ink and ordinary Woodbury printing; and we have, further, this advantage—that by modifying the quantity of colouring matter in the ink the scales can be arranged to suit negatives or transparencies of any degree of intensity. Such scales printed upon thin plate glass or even paper may be cut into strips, and each printing-frame in the establishment may be provided at a very small cost with its own photometer.

GELATINE TRANSPARENCIES.

After numberless trials with gelatino-bromide for transparencies for the optical lantern I have at last met with some degree of success—due, I believe, to the plates employed combined with a suitable developer. For the plates the formula I find to be best is:—

A.

Brom. ammon.	120 grains.
Water, distilled	4 ounces.
Gelatine, Nelson's No. 1	60 grains.

B.

Nitrate of silver	200 grains.
Water, distilled	4 ounces.

C.

Gelatine, Nelson's No. 1	200 grains.

Raise A and B to boiling-point; add B in about eight or ten portions to A, shaking briskly after each addition. Put into boiling apparatus, and after the water has boiled for six or eight minutes cool down and add C.; set and wash thoroughly. *I hold to the necessity of very ample washing.* If the formula be carried out exactly as above the plates will be found to be rather slow, which is an imperative condition of success; with quick plates it is most difficult to get satisfactory results.

I use Ross's four-inch symmetrical to reduce 5×4 and $7\frac{1}{4} \times 5\frac{1}{4}$ to lantern size, with an exposure, on an overcast day at this season, of from half-a-minute for a thin negative to as much as four minutes for a dense one.

The developer is that of M. Audra, lately given in these pages. The proportions I find best best are—

D.

Neutral oxalate of potash	1 ounce.
Water, boiling	3 ounces.

E.

Protosulphate of iron	3 ounces.
Tartaric acid	48 grains.
Water	10 ounces.

Add one of E. to three of D.

Develope until details are out and the dark portions are black, taking care not to veil the high lights, such as sky, water, &c.

Fix in a *fresh* solution of hyposulphite of soda. Should the transparency show any opalescence after washing, a few minutes' immersion in a dish of the following solution will completely remove it, and brighten the picture:—

Citric acid	½ ounce.
Alum	1 "
Water	8 ounces.

J. C. Stenning.

AN IMPROVED CARRIER FOR LANTERN TRANSPARENCIES.

The lantern-slide adapter or carrier which Mr. Alexander Cowan exhibited last week at the technical meeting of the Photographic Society of Great Britain is, we think, destined to prove of great value, if not of eventual universal adoption; and we again draw attention to it in a further and stronger manner than could be done in the report of that meeting which appeared in our last issue.

The success of a lantern entertainment depends in no small measure upon the manner in which the pictures are projected on the screen. Up to a period which may be roughly enumerated as twenty years ago each photographic transparency was mounted in a special wooden frame, and the act of making these appear in succession was a rather clumsy and laborious one, the withdrawal of each slide from the firm spring-grip of the lantern, followed by the slow, "jerky"-like insertion of its successor, being plainly visible on the screen, while the picture was finally "adjusted" in its place by one or two tentative motions. This state of matters was terminated by the introduction of an adapter by our predecessor in the editorial chair of this Journal, who, about the time mentioned above, described it, with a drawing, in these pages. This, under various trade designations, has been the adapter in use up to the present time, its principle of action being that, when the adapting-frame was once inserted and adjusted in the lantern, unmounted transparencies could be passed through the aperture in the end of the frame, and pushed in succession to the other end, with the absolute certainty of each being perfectly centered as it passed the aperture in the middle of the adapter. This useful carrier, after enjoying a lease of life for nearly two decades, is now, in our estimation, destined to be superseded by one which we believe to be a great improvement on the old form.

For several years past endeavours have been made, with more or less success, to have the pictures in a single lantern to succeed each other with a degree of rapidity suggestive of the idea "quick as a wink." The principle of action in such endeavours—several of which have proved quite successful—is to place the carrier in a vertical position and allow the pictures to fall by gravity, a check being interposed to cause them to remain in succession in the axis of the condensers. But the objection to such an arrangement is that almost all lanterns are constructed with special reference to the pictures being inserted not at the top but at the side. It was upon realising the force of this objection, made at a meeting of one of the societies upon the exhibition of an adapter by Mr. J. M. Turnbull, of Edinburgh, that Mr. Cowan fell under the influence of the happy inspiration which resulted in the bringing into existence, within a few days afterwards, of the carrier which forms the subject of these remarks, and which we shall endeavour to describe from the brief glance we had at the solitary specimen then existing.

Let the reader imagine a modern frame sufficiently long to take in two lantern pictures, which are inserted in grooves, these pictures being placed edge to edge, and, of course, separated from each other by the central division between them, the framework assuming the following form . This skeleton frame, with its two pictures, slides easily from one end to the other of an outer frame in which it is contained, and in which there is only a central aperture. The sliding movement is effected by the pulling of a string which depends from each end, or nearly so, of the external frame, and is attached to the internal or running frame, the adjustment being made so as to bring each picture in turn directly opposite the central aperture and no farther. But, owing to the top of the fixed frame being cut away towards each end in a slanting direction, it is now easy to remove the slide that is not in the centre, and drop another in its place. This having been effected, the string at the opposite end is pulled, when, with the velocity of a dart, the new picture is shot into the place of the former one, which, in turn, is now lifted out of its grooves and a new slide inserted. This to-and-fro motion goes on with the greatest simplicity and rapidity until the supply of pictures has become exhausted.

At the time we conversed with Mr. Cowan he had not then had time to devise the means of instantaneously darkening the screen during the fraction of a second required for effecting the changing of the pictures, but he was about to effect an automatic arrangement for doing so. From the well-known mechanical ingenuity of this gentleman we have no doubt of his success. But in the meantime, and whether this last-mentioned addition be completed or not, the carrier, even in its existing state, is the most convenient we have yet seen.

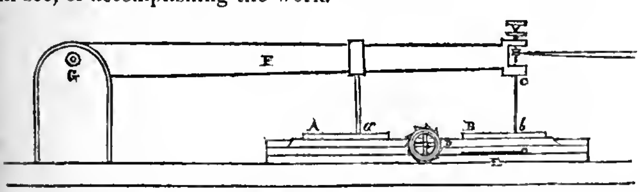
MACHINE FOR CONVERTING WOODBURYTYPE RELIEF INTO TYPOGRAPHIC BLOCK.

A favourite idea of mine was, I observe, spoken of at one of the Cantor lectures. Mr. T. Bolas, F.C.S., is reported to have said, at the lecture delivered by him at the Society of Arts in connection with advancement in photo-mechanical processes, that "he believed there was a still greater development to be looked for from processes in which the Woodbury relief was converted into line and stipple."

Now, as this very subject has been to me a "thinking point" for over twelve months, and as I have a machine partly constructed by which I expected to have been able to say "I have done it!" I may be excused if I desire to put on record my proposed method of converting a gelatine relief into a line printing-block. If any process already exists for this purpose I am quite ignorant of it. The machine I am to describe is purely the outcome of my thoughts on the subject. As this will probably meet the eye of Mr. Bolas I shall be obliged for his opinion as to its practicability.

The character of the printing-block produced by the machine will be somewhat different from an ordinary woodcut, as the lines will be all in one direction. Difference in shade will be represented solely by difference in breadth of the lines—the very highest lights having extremely fine lines or no lines at all, whilst the points of deepest shadow will have lines of maximum breadth or merged lines.

The machine is a very simple one, which cannot fail, so far as I can see, of accomplishing the work.



A, is the relief; *a*, smooth point resting on same. B, prepared plate-block, such as is used for stereotyping purposes; *b*, point of drill resting on block; *c*, very finely-pointed V-shaped drill.

The relief and the block are both on a table capable of motion sufficient to traverse the whole breadth or length of the relief and block. D is a toothed wheel with screw, which is capable of giving a motion exactly at right angles to the other—the whole forming, in fact, a mechanism like the slide-rest of a lathe. F is a metal or wooden beam hinged at G.

Now, it will be evident—if the relief and prepared surface be moved, the relief under the smooth, round point, and the prepared surface under the drill point, which is revolving at high speed—that as the point at *a* is raised or lowered the drill will produce either a fine or a broad line, due to the action of the V-shaped point.

If, further, as each line is formed a pawl, E, causes the toothed wheel D to revolve, bringing a new part of the relief and prepared surface to be operated on, there will at last be produced an exact copy of the relief, with this difference: that its heights and depressions are accurately represented by breadth of lines on a plane—the thing wanted in a typographic block.

This is the machine in its simplest form. It may be modified in a number of ways, such as the substitution of a V-shaped cutting tool in place of the drill, in which case the prepared substance at B would require to be easily cut—soft, yet brittle, somewhat after the nature of Chinese wax—which could be afterwards electrotyped. Another modification, and one which would probably form the best machine, is the multiplication of the lever F with its attachments, and abolition of D with screw. This would allow of a copy or matrix being produced with one movement of the table. The downward pressure in this case might be produced by a series of spiral springs or by one large electro-magnet. Other modifications might be introduced without departing from the nature of the invention.

G. D. Macdougald.

LECTURES AT THE ROYAL INSTITUTION.

PHOTOGRAPHIC ACTION.

Captain Abney commenced his course of lectures at the Royal Institution on Saturday last with a fairly-large and appreciative audience. The afternoon audiences, as a rule, are not of a demonstrative character, many *habitués* apparently attending courses for the sake of an hour's undisturbed nap. The lecturer had, however, provided for this emergency by detonating a chlorine and hydrogen bulb as a commencement of his series of experiments about half-an-hour after his preliminary words. The opening subject of the lecture was on

The Structure of Matter, and on Molecules and Atoms.—The character of a molecule was stated, according to Sir W. Thomson, to be somewhere between $\frac{1}{25000000}$ and $\frac{1}{250000000}$ of an inch, and that in solids and liquids they were separated by a distance which could not be more than $\frac{1}{12000000}$ of an inch, nor less than $\frac{1}{250000000}$ of an inch. An idea of the coarse-grainedness of molecules was given by the fact that the best microscope could enlarge an object from 6,000 to 8,000 diameters, and that if this enlargement were again magnified to the same amount the structure of a drop of water would be seen. The atoms composing these molecules, it was stated, might, as a good-working hypothesis, be supposed charged with energy of some kind, either positive or negative, much in the same way that the ends of a magnet were charged, only with this distinction—that the atom had only one kind of energy, either positive or negative, and not both. An interesting experiment to illustrate the arrangement of atoms was made with needles which had been equally magnetised, the eye-ends of which were fastened to small corks. These were floated on a dish of water, and shown in action on the screen. When a magnet was brought near them they arranged themselves in groups, or when a current was passed through a coil of wire surrounding the basin the same action was visible. By moving the magnet or the coils an oscillation was given to the small floating corks, imitating the oscillations of the atoms and the molecules.

The lecturer next showed how radiation affected these vibrations, explaining the action by the well-timed impulse given to the atoms by the ethereal waves of certain lengths. Using a pendulum to illustrate the action, he showed that by properly-timed puffs of air from a bellows the swing was increased. By increasing the swing of the atoms the amplitude was so increased that it got within the region of attraction of another molecule, and thus left the first molecule, which indicated the necessity of having some substance present which would readily absorb the liberated atoms. The time of oscillation of the atoms was said to be about $\frac{1}{7000000000000000}$ of a second. The ease with which the atoms could be separated one from another could be judged by the energy with which they combined. An experiment of powdered silver and powdered antimony sprinkled into a jar containing chlorine illustrated the lecturer's theory, the former becoming red-hot, whilst the latter became white-hot, immediately they came in contact with the gas.

The production of sub-chloride of silver and chloride of silver was then touched upon, an experiment illustrating the production of the former before the latter being carried out by immersing precipitated silver in a liquid (probably cupric chloride) which readily gave off chlorine. The final experiments went to show that the prolonged action of light could be recognised by chemical analysis—by applying some chemical reagent which has a greater affinity for certain atoms in the altered molecule, and in which, consequently, the atomic energies took up the most stable positions; by a change in colour, as in the darkening of silver chloride; and by rendering inert matter either insoluble or soluble in water by the decomposition of the molecules by light.

These examples, which the lecturer took to show thus, were—1. The explosion of a chlorine and hydrogen bulb. 2. The development of uranium paper. 3. The development of iron paper with gold and silver and ferrocyanide of potassium; also, a platinum print was developed for the same purpose. 4. The development of a carbon print. With these experiments the lecture came to an end, the audience seeming more interested, perhaps, in the practical demonstrations than in the drier scientific part.

The next lecture, according to the very short syllabus placed in our hands, should be on the *Rapidity of the Effect of Radiation and the Physical Development of the Molecular Changes.* We believe, however, that a further short reference will be made to the printing action of light.

ACTINISM *VERSUS* WAVE-LENGTHS.

In this controversy I am placed at a great disadvantage, because in justice to your other contributors I ought not to take up so much space, as I know that, possibly, this subject is interesting to only about one in twenty of your readers. For this reason I endeavoured to make the explanation of my theory as short as possible, and because I have given no proofs of it, in the way of experiment, Mr. Debenham and others seem to think that it is mere guesswork on my part. The theory of the two forces has been built up gradually in my mind by reading various books on physics, photography, light, heat, &c.

If we take the question of absorption alone, I should have to quote the experiments of Forbes, Leslie, Tyndall, Pictet, Saussure, and many others, and then show what bearing each had on the question. This alone would require at least twenty pages of this Journal, which is, of course, impossible for me to obtain, because, as I said before, the discussion would be of interest to so few. I do not think for one moment that I have been able to unravel the whole mystery of light, and have explained in about two pages of the Journal what has puzzled the greatest thinkers and experimentalists of generations past, and concerning which dozens of books have been printed. But I wish to say, in reply to the note by "Free Lance," that I have never seen any articles by Mr. W. Harding Warner—or, indeed, of anyone else—that were in any way similar to the theories I have set forth. If anyone has previously come to the same conclusions that I have I was totally unaware of the fact, and I shall be only too pleased if my theory will support theirs or theirs mine, because, after all, what does it matter who finds a thing out? Photography gains by the fact being discovered. It is sad to hear at our meetings, &c., these continual cavillings as to who first proposed this, or if that is not a "crib" from someone else. It seems to show narrowness of mind. If time prove that my theory that actinic force is a counter-force to colour, and *vice versâ*, be correct, the credit is due to the writers and experimentalists of the past. I have simply built up a theory on their discoveries and experiments. And it is nearly the same with my theory of the action of light on a sensitive film, though I have experimented on this subject more. If my theories are proved to be wrong the subject seems to have raised some interest, to judge from the last few numbers of the Journal; and if through my having raised the question a correct explanation be found for the action of light on a sensitive film I shall not have written in vain. I have simply tried, to the best of my ability, to help other workers in the art I love so much, and we all know that there are plenty of difficulties in connection with photography yet to be overcome.

Mr. W. E. Debenham asks me how my objection to the absorption theory regarding coloured media, on the ground that no discoverable work (expansive or chemical) has been done by the light, holds good in the case of an opaque or black body. Does Mr. Debenham think that because the eye cannot see a colour nothing is reflected from a black surface when light strikes it? Is it possible that the force in light, which travels at a velocity of 192,500 miles in a second, can be absorbed and annihilated without reflecting anything? I think that the black substance has made the wave-lengths so much longer, and they are so lowered in refrangibility as to be beyond the visible range of the spectrum. Does not this explain why light reflected from a black surface has less actinic power than from a red—namely, because the wave-lengths of the dark-heat rays being longer are a greater counter-force to actinism?

I will take one of Professor Tyndall's experiments, made during his lectures on *Light,* delivered in America in 1872-3, to explain what I mean. He showed that a black ribbon, when passed through the spectrum, was found to quench all its colours; but at every stage of its progress an amount of heat was generated in the ribbon exactly equivalent to the light lost. Is not this the reason, viz., that the black ribbon had *altered* the wave-lengths of each colour so that they were changed into dark heat rays beyond the visible spectrum? If it were not so, how could heat be generated? In this case we have long wave-lengths and little actinic power; but, if we remove the black ribbon and put a white one in its place, at the violet end of the spectrum we shall find great actinic force and short wave-lengths. In the first case the rays of light had passed through the prism, and the blue and violet rays had still the great actinic power in them until they reached the black ribbon.

Now, according to the absorption theory, the ribbon absorbs or annihilates not only the various colours of the spectrum but the actinic force that has also passed through the prism, and to the eye and a sensitive film this would appear to be so; but Professor Tyndall shows that heat has been generated, so that the forces which produced the various colours of the visible spectrum on the white ribbon, instead of being absorbed by the black one, must have produced the long wave-lengths of the invisible heat rays. And does not this prove that my theory—that any substance which transmits or reflects light at one wave-length, instead of absorbing the other rays of the spectrum, brings the whole of them to this one wave-length—is correct? If it were not so, when light passes through red glass the latter would have to annihilate not only the other rays of the visible spectrum and their actinic power, *but the heat rays of the invisible spectrum as well.* Professor Tyndall's experiment, however, shows that they cannot be annihilated, so the short wave-lengths of the violet and the long ones of the heat rays must have been brought to one length by the glass; and does not the spectroscope show us it is so—at least as regards the visible spectrum?

Would Mr. Debenham kindly explain what he means by "black rays?" I have never heard the term before. Does he mean the ultra-violet or the dark-heat rays? As to his remarks on Mr. A. Cowan's dark-room lamp: it will be remembered that the sentence that Mr. Debenham quotes was in a reply to a question of Mr. Macdougald's as to whether the law of inverse squares applies to actinic force as it does to luminous power. The question as to how the light was produced was another matter; the only reason why I stated the results of Mr. Cowan's experiments was in their bearing on the law of inverse squares. I may say, however, that I was not at the meeting when that gentleman's lamp was exhibited. I gained my knowledge of it from the short description in one of the journals, *written by Mr. Debenham himself,* in which he stated that Mr. Cowan had taken the idea of the tin shade and reflected light from the lamp I had exhibited some weeks previously.

Mr. Cowan has demonstrated that reflected light through yellow paper and green glass is 180 times safer than when transmitted through the usual red mediums: and as Mr. Debenham has never proved or claimed that these substances combined were anything like 130 times safer than the red by transmitted light, I was perfectly justified in saying that with reflected light we may have over fifty times more light in the room to work by than by transmitted light. I explained, further on, that the reason was that in the latter case a good deal of the light was reflected back into the lamp. If Mr. Cowan will kindly expose a plate of the same rapidity without the tin shade, we shall then be able to know how much of the safety of the light is due to reflection and how much to Mr. Debenham's combination of mediums. Will Mr. Debenham please state what authority he has for saying that my assertion that reflected light is fifty times safer than transmitted light was a mere "unproved guess?"

I regret that when such a good judge and scientific investigator as Mr. Leon Warnerke showed the advantage of reflected light it was not taken up at the time; but until I saw Mr. Debenham's article I was not aware that a reflecting lamp of any kind had ever been exhibited. Still, what does it matter from whom Mr. Cowan got the hint, if we have a safer light to work by than we had before? That is all I care about, and I am sure Mr. Warnerke will feel just the same.

I must apologise to Mr. Macdougald for not answering his interesting questions now; but I have just come across some experiments by Professors Bunsen and Roscoe, in which they unite chlorine and hydrogen under the action of light to form hydrochloric acid. This seems to have an important bearing on one of his questions, so I will leave them all for a separate article. HERBERT S. STARNES.

GENERAL NOTES.

[A communication to the Bristol and West of England Amateur Photographic Association.]

In accordance with the request of the Secretary, and feeling it advisable that each member should make some exertion, however small, to promote the interests of the Society, I have proposed to make a few remarks, as the result of reading the journals—from which something new is always looked for; but this paper avowedly traverses old ground.

I find I have marked a considerable number of places as the journals were perused; but, being so numerous, they can only be touched upon in a very general sort of way. We are concerned more especially with the gelatine process; and if a beginner were to turn over the pages of the journals to know what to do, or if an old hand were to refer to them trying to discover the best process, he would be rather puzzled with the amount and variety he had to deal with. Even in the present day, if the question—What plates do you use, and how do you treat them? were to be answered by different people, the person seeking information would have a variety of answers.

To show how the subject of development alone has been discussed, I have a list of what I noted in the journals, showing that during 1882 in THE BRITISH JOURNAL OF PHOTOGRAPHY there were twenty, and in the *Photographic News* for 1882 there were nineteen, articles; and in 1883 in THE BRITISH JOURNAL OF PHOTOGRAPHY there were fifteen, and in the *Photographic News* ten, articles.

A very great deal has been written regarding the gelatine process, but, notwithstanding, what strikes me as being very peculiar is the small variation between the make and treatment of a gelatine plate in 1873 and one in 1883. Much of the discussion has been owing, no doubt, to the different material with which writers and experimentalists have worked; for instance, the propotions of an emulsion had been given, and when people came to try it they commonly used their own developer, which, the chances are, was not proportioned as the one used by the person recommending the emulsion, and the same with developers being tried on different styles of plates. The one great advance has been the increase in rapidity, and this advantage chiefly caused the old processes to be laid aside.

In 1873 I dialysed with heat at about 100° for twelve hours; in the present day the heat for emulsification has, in many cases, been increased to boiling point. I have tried most of the processes in their day, the most charming being the collodio-bromide, and if anyone were to produce in the market a rapid plate I am sure there are many who would return to that process. One which I adopted some years ago was making a collodion with silver dissolved in it. I dipped the silver film in a bromide bath, just as the iodised film is dipped in the silver bath, and, after washing off the superfluous bromide, flowed over a preservative and dried. The want of rapidity, however, stopped me; but since our knowledge of the effect of ammonia in the gelatine process I have thought rapidity might now be produced by the addition of ammonia to the bromide bath. I have not tried it, but it is possible that something in this direction might be adopted to increase the rapidity.

For a long time the gelatine process caused much trouble and disappointment, owing to frilling, staining, green fog, and ignorance in developing; but, happily, these are things of the past, although many produce green fog by pyro. development. It can be effectually got rid of by Captain Abney's treatment with bromide of iron and ferrous oxalate.

Regarding emulsion-making and plate-coating: as a communication on the subject is to follow, I will only remark that when I left off experimenting in this direction I found the "cold emulsifying" of Mr. A. L. Henderson, as well as the "depositing system" of Mr. W. K. Burton, easy, and to give good results. I now use plates from a maker, and am saved a good deal of inconvenience.

As respects development: in the year 1881—the first half especially—a great many articles were written, hardly a number of the journals being issued without an article on or some allusion to the subject. Very little alteration has taken place, however, in the nature of the developer. Formerly it was an object to get the developer from anyone who had done good work; but the application of it to some other person's plates was a test which did not always produce the desired effect. No wonder, when reference is made to the leading article in THE BRITISH JOURNAL OF PHOTOGRAPHY of the 3rd August, 1883, showing the different proportions of developers used by the different makers of plates. Experience has taught people now more about what they are using, and the object to be aimed at by altering proportions to suit their requirements, according to light, subject, exposures, &c.; in fact, this has been so generally established that an article on development is rare in comparison, and certainly it does not call forth a discussion, as on former occasions.

I will mention a few of the articles written in THE BRITISH JOURNAL OF PHOTOGRAPHY in 1881 as exemplifying different ideas of the method of using the pyro. developer, and, therefore, giving a selection from which one can choose his own style:—Mr. W. Brooks, April 8; Mr. A. Pringle, April 22nd; Mr. H. Y. E. Cotesworth, May 6; Colonel Stuart Wortley, June 10; and leading article, June 24.

It was the writing of articles containing differences of opinion which, no doubt, encouraged the photographic public to experiment. I think the most generally-adopted plan now (with amateurs at least) is to feel the way with a standard weak solution first, whereby the effect of exposure is ascertained, and to finish by degrees according to circumstances. The latest published formulæ are those of our Treasurer, Mr. Brightman, in the *Photographic News* of December 14, 1883, and of Mr. H. Manfield in the *Year-Book* of 1884, page 85; also one by Pierre Revan, in the *Photographic News* of November, 30, 1883. Each point to the same treatment—"slow development;" but whether this will not be questioned by someone recommending the development to be strong and quickly over remains to be seen. One which has the characteristic of not staining dishes, as well as giving a difference of tone, will be found at page 149 of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1883, by Mr. Thomas Farnell, who publishes one in THE BRITISH JOURNAL OF PHOTOGRAPHY for October 5, 1883, in which he says green fog is prevented altogether. If so, it will be a boon to many. The peculiarity consists in treating the sulphite of soda first with alum.

There are many advocates of the ferrous oxalate developer, and the question as to which is the best developer might be practically tested when the outdoor meetings are held by taking duplicates of a subject, and developing one by pyro. and the other by ferrous oxalate, the negatives being exhibited by the different members. This would be a matter of curiosity and create some interest. Formerly—in fact, till lately—when a plate was cleared in the hypo. it was considered finished, and properly ought to be. But in cases of miscalculation we now have at command subsequent treatment, and clearing it from stain, reducing and intensifying are resorted to; in fact, a gelatine negative is now so under control as to be finished according to the standard of one's own fancy.

To say what is the *best* way of the many to make a gelatine plate and develope it can only be looked for when it is discovered that one maker's plates are superior in every respect to another. Some approximation, however, might be obtained if medallists could be induced to mention the makers of their plates and their treatment of them—I mean specially as regards landscapes; but I fear this high road to perfection would detract from the interest of those who take a pleasure in experimenting to overcome difficulties. Even much could be learnt among ourselves if (say) a particular subject in the vicinity were selected, and a competition for the best negative and print were to take place. The effect of different makes of plates and developers would then be apparent. A comparison of results, knowing the details of how they were manipulated, would tend to increase our interest. I think it would give a stimulus to our work, and be productive of the best results. COLONEL PLAYFAIR.

ROUND AND ABOUT SNOWDON.

[A communication to the Birmingham and Midlands Institute Scientific Society.]

OF the many thousands of holiday-makers who yearly visit our native Mont Blanc, the greater number attack it from the side of Llanberis. Here, newly arrived by train, the unsuspecting visitor is beset by swarms of boys who importunately offer their services as guide to summit, waterfall, or apartments, till the tourist is driven to the verge of distraction. If, as is probable, he deem it his duty to struggle to the summit, and the weather seem tolerably clear, he starts off up a long tedious road until at last, when he attains an altitude which should yield him some views to reward him for his exertions and encourage him to further efforts, too frequently the misty clouds come sweeping up, and, folding him in their cold embrace, bid hope depart from his soul. He then returns to the lower regions with no other satisfaction than that of gratifying a good appetite.

As a contrast to this, let lovers of natural scenery do as I, accompanied by the partner of my joys, did last summer—that is, go by the Snowdon Ranger line round to the back of Snowdon, attack the mountain from the Glaslyn side, and return by Llanberis.

We had been one morning to visit the celebrated Aber Falls, and in returning to the station found that we had an hour to wait. We went to see the sea, but found that it had gone out for the afternoon over to Beaumaris, so we returned to the station and whiled away the time by reading the placards—a proceeding which the company kindly facilitated by delaying the train nearly an hour. Amongst the announcements was one of a tour round Snowdon, which undertook to convey the tourist by train to Pont Rhyddu, thence by coach *viâ* Beddgelert, Nant Gwynant, and the Pass of Llanberis. Although I have a strong objection to being "personally conducted" anywhere that a map and a compass will take me, the idea of getting to Beddgelert was not to be resisted, so a two-day excursion was fixed for the next morning.

An early hour accordingly found us in the train from Penmaenmawr to Bangor; and it is worth noting that if you wish to travel by parliamentary trains on Welsh railways you must get up early. The morning was dull and the clouds rested so closely on the Carnarvonshire hills as to give little prospect of any ascent of Snowdon; but, still, whatever the weather may be to the geological or botanical student, there is always plenty to interest in a new district among the mountains. At Bangor I asked for Beddgelert tickets, but only received those for Pont Rhyddu, although Bradshaw gives the fares to the former place. We pass Carnarvon, and then alighting at Dinas we perceive a little toy engine, with three diminutive carriages to match, standing alongside the platform. These belong to an old mineral line, which although only of a very narrow gauge has been adapted for passenger traffic. The train of course travels only at a slow rate, and you are requested to keep your heads inside the carriage lest you should knock down the bridges. We get into one of the little wooden boxes amidst a liberal allowance of Cymric from our fellow-passengers; the little engine buckles manfully to, and with much snorting and bunting we get into motion.

The first part of the journey is flat and uninteresting. The fields bordering the line are swampy and stony, showing little sign of cultivation. Presently we arrive at a junction, for this little line, like its more pretentious brethren, rejoices in the dignity of a branch. Passing on by Bettws Garmon the hills begin to close in upon us, and the way becomes steeper and more winding. Next we catch sight of Nant Mill, with its waterfall, on our left, and begin to wish we were walking instead of riding; but we make a note of it for a future occasion and look ahead. Here we see coming into view Llyn Cwellyn—a fine sheet of water one mile long and a-quarter of a mile wide. The train runs along on the left-hand side of the lake, and at about halfway along it stops at the Snowdon Ranger station. This station takes its name from the adjoining inn, and claims to be the nearest one to the summit of Snowdon. This is, indeed, only four miles away, and can readily be ascended from this point.

A good view of the mountain should be obtained from here; but on the present occasion the monarch is shrouded in mist, though Mynydd Mawr, a 2,300-feet mountain across the lake, stands out clearly. Two miles further on we come to the present terminus of the railway, Pont Rhyddu, where we find two brakes waiting to receive those going on to Beddgelert, and since there are only two other passengers, clerical tourists, we are easily accommodated. The distance is only four miles, through a tract of wild and desolate country. Scarcely a house is to be seen, and the wind blows chillily across the watershed. We pass another small lake, Llyn-y-Gader, and presently see the Pitt's Head rock—a large detached boulder by the roadside, presenting a rude likeness of that renowned statesman; and, lest the tourist should miss the treat, some public benefactor has painted up on both sides of the stone the word "Pitt" in large letters.

The road now declines by the side of a stream coming down from Snowdon, and the scenery becomes more softened, until we arrive at the celebrated village of Beddgelert. Resisting the inviting aspect of the numerous hotels, we step out at a brisk pace to warm our stiffened limbs, and, passing the supposed grave of the faithful hound, make for the famous Pass of Aberglaslyn. Before, however, we have got far the pangs of hunger become irresistible, and, sitting down by the side of the rushing river, we bring out the trusty sandwich tin. Having refreshed ourselves we continue our walk, and now the sides of the valley narrow in closely upon us, and the frowning precipices convince us that the title of "Pass" is really deserved far more than by any other pass in Wales that we have yet visited. The road rapidly descends by the side of the now foaming torrent, in marked contrast to the flat plain on which Beddgelert is situated. It is plainly evident that where that village now stands once existed an ancient lake, and that since then the river has cut its narrow channel through the barrier of rock closing it in, and thus drained and exposed the alluvial deposit previously laid down by itself.

The way grows continually grander. The road has only gained a footing by being built up out of the bed of the stream, which forms a continuous series of cascades beneath us, and we arrive finally at Pont Aberglaslyn. Here, standing on the old, romantically-situated bridge, we look back up the pass and revel in the scene before us. The pass lies in front of us, the mountains rising up and appearing to actually bar the progress. The road, as I have said, built up out of the gorge winding with the stream; the white foaming water of the latter coming tumbling over the boulders; the beautiful dark fir trees clothing the sides of the valley—all combine to form a picture never to be forgotten.. The scene is indeed one to bear comparison with many a famous valley in Switzerland, and we lose no time in getting out the pocket camera and converting "a thing of beauty" into "a joy for ever." We scramble down the sides of the chasm and admire the luxuriant growth of ferns from every crevice in the rock; gaze into the dark pool below the bridge, so inviting to a bath, and wish that we could spend the whole day here. But we have made up our minds to try to get to Penygwryd for the night, and so retrace our steps to Beddgelert. Here we get on a coach which will convey us through the beautiful vale of Gwynant, which well deserves a chapter to itself; but I have lingered already so long that I must pass rapidly over it.

The top of a coach is well adapted for seeing the landscape, but the scenes change so rapidly that one has to be continually on the alert and the beautiful spots have not time enough to soak in. Moreover, as the evening comes on the wind blows cold in these valleys, and it is with a feeling of relief that we catch sight of Kingsley's beloved hostelry of Penygwryd. Here, after a wash and hearty tea, we feel "like giants refreshed," and sally out to make the most of the evening.

Having resolved on the morrow to descend the Pass of Llanberis, we determine to visit the lakes of Llyddaw and Glaslyn. These lie on the route to the summit of Snowdon; but we have little expectation that the mist will clear off from the peak, even on the morrow. To our surprise, however, after we have climbed to the summit of the Pass, and, leaving the main road, wander round the shoulder of the mountain, we catch sight of Y Wyddfa clear before us. We shortly meet a gentleman who has come down from the top, and reports that it is quite clear. We wish now that we had started sooner, but resolve to press on as far as we can ere the shades of evening overtake us. We pass the little lake of Llyn Teyrn, and note how the rocks on our right have been planed and scored by the ancient glaciers which descended from the crown of Snowdon. This whole hollow is, indeed, intensely interesting to the student of the glacial epoch. The flora also begins to assume an aspect unfamiliar to dwellers in lowland plains. The Alpine clubmoss points out to us that we are arriving at a height of 2,000 feet, whilst on every piece of boggy ground the yellowish leaves of the Snowdon violet stand out like so many stars.

We arrive at Llyn Llyddaw, and here the question presents itself to us how we are to get across, for the path leads straight into the water. In order to save the circuit of the lake a roadway has been built up from the bottom; but when the lake is full, as on the present occasion, the water overflows it, and in order to accommodate foot passengers a number of stones have been placed along one edge of the path for them to walk upon. The stones have a disagreeable rocking propensity, and, the water being a foot deep on the horse-track and an unseen depth on the other side, the prospect in case of a slip is not assuring. However, we get safely over, and continue ascending alongside the lake. The precipices of Lliwedd stand out grand and gloomy over on the other side, and we think with awe of the fatal fall of our townsman from those dreadful heights. As the road bends round the mountain we turn round and survey the scene behind us. The prospect is a delightful one. We are ourselves in deep shade, the awful precipices around us cutting off so much of the sky. Across the rippling waters of the lake, however, the sunshine is falling placidly on the farther side of the Valley of Gwynant and Moel Siabod in the distance; but the declining light warns us to hasten our steps.

We toil steadily up the old miners' road, with their old deserted buildings as our landmark, whilst the stream comes bounding in cascades to meet us. Snowdon has again put his nightcap on, and when we at length arrive at the upper lake, Llyn Glaslyn, the scene is cold and dreary. We walk to the upper end of the lake, along the ruined tramway with lumps of ore still lying about it, take a wondering glance at the steep path which leads to the final ascent to the summit, and then face homewards. Half way along the lake, however, our attention is arrested by a fine example of a perched rock. Left by the old glacier, as it wasted away before an ameliorating climate, on a boss of rock which has been rounded and smoothed by the same agency until no plant can get a footing upon it, there the old boulder stands, grey with age and split across by the action of numberless frosts, on a spot which must carry conviction to the most sceptical of geologists, for, from the position in which it stands, it could not possible have rolled down to where it now rests from any superior height. This is too good to be neglected. The camera is again brought into requisition, a good long exposure given, and then without further delay (for we think of the walk across the lake) we trot rapidly down the hill, get back to the hotel, and go to sleep, with the sensation of having by no means lost a day.

The next morning we are out early to inspect that all-important factor—the weather. The white clouds are lying low on the Glyders at the back of the hotel; but the bright sunshine gives promise of their eventual dispersion. After breakfast we take a vehicle down the pass of Llanberis. Whether, however, our hopes had been raised too high, or that passes should always be viewed ascending, certainly it was that we were rather disappointed with this one. After passing the summit of the pass we look out for the noted perched block up on the right, and our driver presently points to a very diminutive-looking stone up aloft, saying at the same time that it is a long way up. We scarcely credit this latter, it seems so close in the clear morning air. I get down, and, camera in hand, go vigorously for it. I am, however, soon convinced of our driver's superior knowledge, and have to stop several times for breath before reaching it. Still it is worth the climb, though the ground is rugged and sometimes boggy. The block is about nine feet high, and stands on the very edge of a massive bastion of rock, in such a position that it would surely not have stopped if it had rolled down from above. The rock, moreover, on which it rests has been unmistakably smoothed by the touch of glacier ice, and shows thus to what a great depth the valley was formerly filled up by that sluggish current.

The picture taken, a rapid but cautious descent brings me again to the road, and we continue our journey down to the Cromlech Bridge. This takes its name from some immense blocks of stone by the roadside, which, however, are not true cromlech stones, but are simply parts of an immense fall of stone from the Glyders. Indeed, this side of the pass here presents, as high as the eye can reach, one continuous straight slope of talus from the rocks above, and which is waiting for the next glacial epoch to be borne away; for I think it is a mistake to suppose that a little mountain stream can ever roll away the *débris* continually showered into it by the side of a valley of any width. Lower down on the left some rocks, plainly glacier-rounded, point out the *embouchure* of Cwm Glas—a hollow well worth visiting by the student of glaciology—and we presently catch sight up it of the peak of Snowdon standing out clear against the sky.

Arrived at Llanberis, we first go to see the beautiful waterfall formed by the stream coming down from Snowdon, and which must, by all means, be viewed from its own left bank. There being no means of crossing the water, we are compelled to retrace our footsteps for some distance before we can get upon the Snowdon ascent proper. This calls for little remark; for, as I have already said, it is about the most monotonous road that could be taken, there being no view until the top of Cwm Glas is reached, where we look down into the Pass in the reverse direction to that before mentioned. The road is quite clear below us. The Glyders stand grandly opposite us, and the sound of blasting reverberates across from the Llanberis slate quarries. The ascent now stiffens. We pass the junction with the road from Penygwryd, where we see the little lake of Glaslyn again, but lying far below us; and, striving against the strong blasts which now encompass us, we gain the summit. Here the first objects which meet us are our fellow-tourists of the day before, who have come up from Beddgelert, and whom we greet with the friendly feeling we always acquire for those with whom we travel for even a short time.

Having ensconced ourselves under the trigonometrical cairn, we endeavour to count the numerous lakes in view, check off the mountains, and strain our eyes on the low, black bank presented by the Isle of Man, the under-surface of the clouds cutting off, like a drop scene, all more distant views. But the clouds come and enfold us, chill us through, and make us take refuge in the sheds, where we have refreshments; but let me draw a veil over that. We take some more views, with vain endeavours to get a lull of a few seconds in the wind. and then rapidly descend the mountain. As the evening closes I go to the base of the old Dalbadarn tower and enjoy the beautiful scene here spread out to my view. The lake before me, beautiful, though much disfigured by the immense masses of *débris* sent down into it from the slate quarries, which rise terrace-like above it on the other side, the lower lake gleaming in the light of the setting sun, and the pass overshadowed by the grey shadows of the coming night, sink deep into my memory. I tear myself lingeringly away, for the time of the last train is approaching, and soon we are on the way back, delighted with our two days' experiences, and hoping that all our friends may be induced to venture on a similar circuit. C. J. WATSON.

SPECIFICATIONS PUBLISHED DURING THE PAST WEEK.

PRODUCING PLATES BY PHOTOGRAPHY TO BE USED FOR PRINTING PURPOSES.

THIS invention, which received provisional protection only, is a communication from Messrs. BENECKE AND FISCHER, of St. Louis, United States of America, and JOHN FRANK, of Frankfort-on-the-Main, Germany.

IT relates to an improved method of producing photolithographic plates for use in printing, and the object is to produce a plate from which a picture or the like can be printed, the shades of which are formed by a number of points or dots placed more or less close together, the design for the picture being engraved upon a zinc or other plate, from which impressions may be taken by pressure. The production of the design is accomplished by taking by photography from a negative a small representation of the object which is to be reproduced. This representation is enlarged whereby a design is produced which consists of a great number of small points or dots, and which is thus in a suitable form to be engraved upon a zinc or other plate in order to be reproduced by pressure. To prepare such a design it is necessary that the collodion employed for taking the representation should be very thin and only slightly iodised, as upon this depends the size of, and the distance between, the points or dots. The plate should have a coarse or a fine grain according as a greater or lesser enlargement of the proof is required.

The liquid, the composition of which is given below, is that which is required for the production of the small image.

Alcohol	30 grains.
Ether	30 ,,
Gun cotton	0·8 grain.
Iodide of ammonium	0·8 ,,

To cause the image to appear or be developed the following composition is used:—

Water	480 grains.
Sulphite of iron	30 ,,
Acetic acid	60 ,,
Alcohol	30 ,,

The shade of the design depends upon the strength of the solution, being lighter when the solution is stronger and darker when the acid solution is weaker. The design can be transferred upon the stone in the ordinary manner, and the picture or the like can be reproduced by lithography.

IMPROVEMENTS IN APPARATUS FOR STORING AND CONVEYING DEVELOPING AND OTHER CHEMICALS REQUIRED FOR THE PRODUCTION OF PHOTOGRAPHIC PICTURES.

THE following is the specification of GEORGE DUNCAN MACDOUGALD, chemist, Dundee, in the county of Forfar, North Britain:—

The object of my invention is to enable a photographic operator to produce, in a rapid and convenient manner, a developing or other chemical solution of adjusted strength, and at the same time to preserve in a more efficient manner the chemical reagents used.

In carrying the same into effect, according to one part of my invention I construct envelopes or vessels made either of glass, paper, gelatine, gum arabic, or a compound of gum arabic and gelatine, or other suitable material, according as I wish to preserve the chemicals in a wet or dry condition, and having one or more spaces inside, in which are placed adjusted quantities of chemical reagents in a solid or liquid state. The envelopes or vessels are constructed in such a manner, hereinafter described, as shall preserve the chemical or chemicals, and at the same time enable the operator at will to discharge their contents, in order to form an adjusted photographic chemical solution.

According to the second part of my invention, and with the same object in view, I impregnate pieces of bibulous material, such as asbestos, ordinary cloth, felt, bibulous paper, or such other substances as are porous in their nature or construction or other material with adjusted quantities of chemical reagents, and afterwards I dry these pieces completely in order to prevent atmospheric action. By soaking one or more pieces of the impregnated material in water a solution of chemical reagents may be made of adjusted strength.

Having thus in a general manner set forth the nature of my invention, I now proceed to describe more particularly the method of working or carrying the same into effect.

According to the first part of my invention a convenient form of the new apparatus consists of a vessel made of glass and provided with two projecting tubes. The chemicals are introduced into the body of the vessel, and the tubes thereafter completely closed or sealed in any convenient manner.

In the event of the vessel being made of glass, the sealing is conveniently performed by melting the ends of the tubes and thus closing them. Other methods of sealing may however be adopted, such as filling the ends of the tubes with wax, pitch, or other substance of a like nature, or by placing small caps on the ends of the tubes, or sealing stoppers into the tubes. A short distance from the ends of the projecting tubes slight indentations or incisions are made, so as to facilitate the rupture of the vessel. In this form of my invention, and in the event of the projecting tubes being made of very small diameter, the incisions or indentations may be dispensed with, as the tubes may be easily ruptured without an indentation. When about to be used the ends of the projecting tubes are broken off. A clear passage is thus made for the escape of the chemicals, which may be allowed to flow out by gravity, or the mouth may be applied to one end and the contents blown out at the other, to form the adjusted chemical solution. By the use of this device a photographic chemical or chemicals may be preserved for any length of time uninjured by air or climate, and at a moment's notice be discharged to form an adjusted, developing, or other photographic solution.

Another convenient form of my invention consists of a vessel made of glass or other material, but without projecting tubes. An incision or indentation is made in any position on the vessel in order to weaken its walls. When about to be used the vessel is ruptured by force applied to its weak part or parts, and the chemical or chemicals thereby liberated to form the adjusted solution.

Another convenient form of my invention consists of a thin bulb or bulbs to contain the chemical or chemicals, and of such material and thickness as may easily be ruptured by pressure.

Another form of my invention consists of an envelope of cylindrical or other form, provided with one or more partitions, for the separation of the various chemicals. These envelopes may be made with a material soluble in water, or with a material insoluble in water and provided with a seam of gum arabic, or other soluble and adhesive substance, which opens by the action of the water, or they may be made of materials altogether insoluble in water. The partitions may be made with a piece of string applied as a ligature, the surplus string being left attached for convenience in after manipulation; or the partitions may be made by the insertion of a piece of paper, cardboard, cotton wool, or other material into the interior of the vessel. When about to be used the envelope is placed in water. If of soluble material the envelope then dissolves, discharging the chemical or chemicals. If of soluble material, and provided with a soluble seam, the seam opens and allows of the discharge of the chemicals to form an adjusted solution. Whether the envelope be made with a seam of soluble material such as gum arabic, or altogether of soluble material, or altogether of insoluble material, a very quick and convenient method of releasing the materials is to rupture the various compartments with the finger nail previous to putting the apparatus into water.

Another convenient form of my invention consists of a paper cylinder with an opening or openings into it, covered with a flap or flaps, which remains closed while the apparatus is not in use, and keep the contained chemical or chemicals in position. When about to be used the apparatus is put in water, when the flaps open, discharging the chemicals.

According to the second part of my invention, and with the same objects in view, I saturate the pieces of bibulous material, such as asbestos, ordinary cloth, felt, bibulous paper, or such porous material as loaf sugar, with adjusted quantities of a chemical or chemicals.

To use this form of my apparatus, the bibulous portion is dipped in water when the chemicals dissolve out, producing an adjusted solution.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is—

1. Vessels made of glass or other material, and provided with one or more projecting and sealed or closed tubes, substantially as and for the purposes described.
2. Vessels made of glass or other material, and provided with one or more incisions or indentations, substantially as and for the purposes described.
3. Vessels made of paper or other material, and provided with incisions or partitions, substantially as and for the purposes described.
4. Soluble envelopes, or such as open by the action of water, substantially as and for the purposes described.
5. Vessels having an opening or openings covered with a flap or flaps, which open by the action of water, substantially as and for the purposes described.
6. Pieces of bibulous material, such as asbestos, ordinary cloth, felt, bibulous paper, or porous material, such as loaf sugar, substantially as and for the purposes described.
7. The combination of two or more of the forms above described, substantially as and for the purposes described.

[From the foregoing we have omitted certain drawings of forms in which the tubes and other appliances may be made, together with references to them, such not being necessary to the understanding of the principle of the invention.—EDS.]

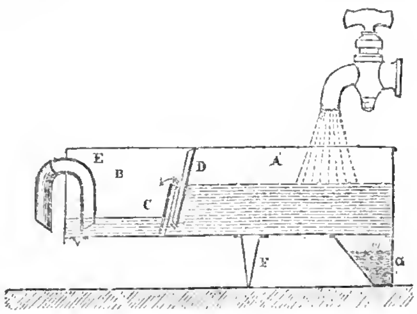
IMPROVED APPARATUS FOR USE IN WASHING PHOTOGRAPHIC PRINTS AND OTHER ARTICLES OR MATERIALS.

THE following is the specification of FREDERICK HAZELDINE, of Lant-street, Borough, in the County of Surrey:—

My invention relates to a simple construction of trough for washing photographic prints, negatives, or chemical compounds, whereby the whole body of the washing water, and particularly the portion containing the salts dissolved out, is changed at frequent intervals with the least necessary waste of water, the operation of the washing trough being entirely automatic without the use of any mechanism.

The trough is divided into two compartments, of which the first or washing compartment receives a constant stream of water that flows from the one compartment to the other, whilst the second compartment is provided with an outlet syphon or valve. The trough is so balanced that when the second compartment fills to a certain height the trough assumes suddenly a tilted position, thereby violently agitating the water among the prints or materials being washed, separating them and starting the syphon or opening the valve. The arrangement is such that the outflow shall gain on the inflow, so that the water will be run off from the second compartment faster than it flows into the first, until the second compartment having been almost emptied the counterpoise preponderates and returns the trough to its horizontal position, again agitating the water, &c., whereupon the trough refills and the same operation is repeated.

A and B are the two compartments of the trough separated by a partition C, which rises from the bottom to within a certain distance of the top of the trough. The compartment A is the larger of the two, and in it are placed the prints or substances to be washed. D is another partition dipping into compartment A at a short distance from partition C, and reaching from the top of the trough to within a short distance of the bottom, so as to compel the water at the lower part holding in solution the salts washed out (and which being of greater specific gravity sink to the bottom of the trough) to pass out through the space between the two partitions C D into compartment B. E is a syphon of which the short leg dips into compartment B, and reaches within a very short distance of the bottom, whilst the bend of the syphon is sufficiently below the top of the trough to ensure the syphon being started automatically when the trough assumes the inclined position. The longer leg of the syphon extends sufficiently below the bottom of the trough to ensure the action of the syphon continuing until the compartment B is sufficiently emptied. The trough oscillates on a transverse fulcrum formed by a downwardly projecting rib or plate F, fixed or hinged to, and extending across, the bottom of the trough, and in its normal position the trough rests partly on the fulcrum F and partly on a downwardly projecting part G at the end opposite to the syphon, which part G is sufficiently loaded to preponderate and to bring the trough back to its horizontal position when



the compartment B is nearly empty, but is overcome when the compartment B fills up to about the top of the partition C, the relative position of the partition C and of the fulcrum F being such as to enable this action to take place by the alternate preponderance of the weight G and the full chamber B. The compartment A receives a constant supply of water so regulated that the inflow is somewhat less than the outflow through the syphon E. A valve may be substituted for the syphon.

The apparatus may be made of tinware or other suitable material, such as earthenware or ebonite, and if of metal should be protected on the inner surfaces against the action of the chemicals.

Having now particularly described and ascertained the nature of my said invention and in what manner the same is to be performed, I declare that what I claim is:—

A photographic or chemical washing trough or tray divided by partitions as described, and provided with a syphon or valve outlet and counterweight, and arranged to rock automatically upon a fulcrum, substantially in the manner and for the purpose herein described and illustrated in the drawings.

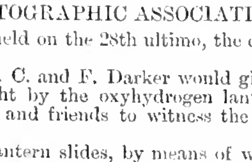
LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the weekly meeting of this Society, held on the 28th ultimo, the chair was occupied by Mr. W. H. Prestwich.

It having been announced that Messrs. C. and F. Darker would give a demonstration of the polarisation of light by the oxyhydrogen lantern, there was a full attendance of members and friends to witness the proceedings.

Mr. A. Cowan showed a carrier for lantern slides, by means of which two subjects could be rapidly and smoothly changed. It differed in principle from the one lately introduced by Mr. Macdougald, in that the slide was horizontal, and therefore applicable to any lantern. The movement was to and fro, and will be found described in our last number in the report of the meeting of the Photographic Society of Great Britain. He (Mr. Cowan) also described some further experiments with green glass and yellow paper as the



media for illumination for photographic dark rooms, and showed some results, from which it appeared that, starting with one thickness of paper, the addition of the green glass did not stop quite so much photographic action as an additional thickness of paper, but that when four or five papers were used the glass prevented photographic action quite as effectually as two or more additional thicknesses of paper.

Mr. W. E. Debenham said that a medium of one colour let through certain rays of light, having a photographic power which further thicknesses of the same colour would still let through. A medium of another colour, however, would stop these rays. In this instance the green glass stopped the orange or red rays, and rendered the light pleasant to work with as well as safe.

Mr. W. Ackland agreed with Mr. Debenham as to the effect of two media of different colours.

A question from the box was read—"Why are not large heads taken direct in the camera instead of by enlargement?"

A Member said that the question would form a subject for an entire evening.

Mr. A. Haddon remarked that the members were now doubtless anxious to see Messrs. Darker's demonstrations, and, as Mr. Debenham was in a few weeks to give a lecturette on lenses, the subject of the question would then, probably, receive attention.

Mr. C. Darker said that it gave great pleasure to himself and his brother to demonstrate before the Society some of the phenomena of polarisation. Many of the slides which would be shown were prepared and lent for the occasion by Mr. Lewis Wright. He would invite particular attention to the effects produced upon bodies by molecular forces, such as attraction, expansion, and crystallisation. Some of the effects of these forces were either made visible or brought into much greater prominence by the use of polarised light, and the appearances so produced could, except as regards colour, be reproduced by photography. Images of crystals—benzoic acid, salicine, and citrate of soda—were thrown upon the screen, with and without the intervention of a plate of selenite, to show the effect of polarisation in displaying the forms of their crystallisation, and photographs of the same subjects taken under the same conditions were handed round. Amongst other substances illustrating the effects of polarisation, there were shown slides of zanthonine, salicylic acid, chloride of morphia, double sulphate of copper and ammonia, tartrate of soda, urea, cinnamonic acid, chlorate of potash, and tartaric acid. Hyposulphite of soda was also shown. In this case a little gum had been added before crystallisation.

Mr. A. J. Brown here remarked that gelatine altered the form of the crystals deposited from its solution.

The subject of the biaxial system of crystallisation was then gone into, and a crystal of nitrate of potash was first shown with its two sets of coloured rings in illustration. Carbonate of lead, with its axes farther apart than those of nitre, arragonite, sulphate of iron, bichromate of potash, borax, and sugar followed. After the exposition of the effect of a right and left crystal of quartz when used together, and an exhibit of amethyst and selenite, the effect of expansion from heating one edge of a plate of glass was shown, and that of pressure upon the same substance whilst in the lantern; and it was mentioned that a photographic lens which was too tightly screwed down into its cell would show a similar effect. Sections of various substances were then shown, and the brilliant glow and change of colour evoked frequent applause. Amongst the subjects giving the most striking effect were perthite, zeolite, and graphic granite.

A display of symmetrical figures from pieces of selenite concluded a most successful and enjoyable evening, and on the motion of Mr. Debenham, seconded by Mr. Haddon, a hearty vote of thanks was accorded to Messrs. Darker.

On the 14th instant Mr. T. Bolas will deliver his lecture on photo.-block printing.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The ordinary meeting of this Association was held at the Free Library, on Thursday, the 28th ult.,—Dr. Kenyon, President, in the chair.

The minutes of the January meeting were read and confirmed, and Messrs. Sharp and Swinton were elected members of the Association.

The Librarian announced the receipt of a donation to the library of the American *Photographic Times*, and of eight lantern slides, on Cowan's plates, from the Rev. H. J. Palmer.

The Hon. Secretary read a letter from the Hon. Secretary of the Sheffield Photographic Society, thanking the Liverpool Amateur Photographic Association for their contributions to the recent Sheffield photographic exhibition.

The Chairman read an addition to bye-law No. 5, which had been made by the Council—"That all prints for competition, or for the exhibitions of the Society, should be mounted on separate mounts, not less than seventeen and a-half by thirteen and a-half inches." This received the sanction of the meeting.

Mr. H. Rutter exhibited some of the cathedral-tinted glass recently brought to the notice of photographers by Mr. W. E. Debenham.

Mr. J. A. Forrest said that this glass, on submission to the test of the spectroscope, proved to be most unsafe for transmitting light to the developing-room. If good pictures were obtained where it was in use it was the result of the merest accident.

Mr. J. H. Day passed round a beautiful transparency which had been developed in a room lit by a naked gas flame, and yet without a trace of fog.

Mr. Rutter differed from Mr. Forrest entirely, and thought that plates might be safely developed where the light passed through glass of the kind described. In practice, however, he preferred to use a sheet of orange paper in addition.

Mr. W. H. Kirkby said that, in his opinion, no glass whatever was absolutely safe for the development of exceedingly-sensitive bromide of silver films; but he thought that the safest combination was that of light ruby glass and a sheet of orange.

The Chairman thanked Mr. Rutter for exhibiting his specimens of the glass in question, and also for introducing the subject. He (the Chairman) proceeded to say that discretion was necessary in the use of light, and when this was employed almost any mode of illumination might be used in the dark room without danger. He then called the attention of the members present to some extremely-beautiful snow pictures, by Mr. Valentine, of Dundee, which he had been good enough to send for exhibition.

Mr. W. Rogers exhibited and described one of Steinheil's new lenses.

Mr. Morris showed some ferns artistically arranged on mounts for photographing.

Mr. J. H. T. Ellerbeck exhibited a number of light and portable frames, invented and constructed by himself, for the display of mounted photographs. These frames were filled with a large collection of prints by Mr. Ellerbeck, as well as with the productions of the Rev. H. J. Palmer, Messrs. Crowe, Forrest, Kirkby, and other members of the Association.

The presentation print of *Chartres*, enlarged by the Woodburytype Company from a negative by the Rev. H. J. Palmer, was on view, and also a fine enlargement by Messrs. Goodall and Steven, on enamelled gelatino-bromide paper, of Mr. W. H. Kirkby's picture, *Tired*.

An exceedingly-interesting comparison of the brilliancy of the discs given by lanterns by different makers then took place. The Rev. H. J. Palmer showed Mr. Medland's Pentaphane; Hughes' Pamphengos was exhibited by Mr. Watts; Archer's Photinus, by Mr. Phillips; and the Triplexicon, by Mr. Knott. The result of the trial showed that the Photinus was greatly superior to the others. This is a new four-wick lantern, with a reflector of a special curvature invented by Mr. Archer.

The Rev. H. J. PALMER called attention to a feature in the Pentaphane, by which enlarged negatives could be taken direct from an ordinary photographic print.

The members then adjourned to the lecture hall to enjoy a large number of views shown by Mr. Knott with the oxyhydrogen lantern. The transparencies were the work of the Revs. H. J. Palmer and Scott, and of Messrs. Beer, Day, Ellerbeck, Kirkby, Maycock, Watts, and others. Mr. Ellerbeck's series of views among the Hartz mountains and on the rivers Rhine and Lahn were much enjoyed; and his comic pictures illustrating Longfellow's poem "Excelsior," which was read by the Hon. Secretary as the pictures passed in succession over the screen, caused much amusement.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE ordinary monthly meeting of this Association was held at the Studio, Portland-street, on Wednesday, the 27th ult.,—Colonel Playfair, Vice President, in the chair. The minutes of the previous meeting having been confirmed,

The HONORARY SECRETARY proposed Mr. Edward Walsh as an ordinary member, and he was unanimously elected.

The CHAIRMAN then read his paper entitled *General Notes*. [See page 152.]

Mr. E. BRIGHTMAN remarked that Mr. Bennett, in the early days of gelatine, did much to popularise the use of gelatine by the introduction of his rapid plates.

The CHAIRMAN said that, although they were practically using the same plates now as in 1873, still the modification of the formulæ, the additional aids to development in the direction of reducing or increasing density, and the increased experience gained had placed them in a vastly-advanced position and given them a control over the results which were in the early days eagerly sought for.

Mr. PHILLIPS inquired if it were generally considered a *sine quâ non* to use the developer recommended by the maker of the plates being used.

Mr. DANIEL replied that such was undoubtedly the case, as the maker, if a reliable one, would have experimented and found what developer gave the best results with his plates. Of course, the particular mode of using the developer preferred by the operator might ultimately be adopted, the quantities suggested by the maker being brought to bear upon the operation of making up the developer.

Mr. BRIGHTMAN expressed his belief in the absolute necessity for different plates being differently treated.

Mr. DANIEL, in support of Mr. Brightman, remarked that for weakening his own plates he found dilute cyanide of potassium acted admirably and was perfectly under control, and yet, when trying it with commercial plates, some were not affected at all by it, while in others the picture was most rapidly destroyed.

Mr. PHILLIPS suggested that one would hardly follow the maker's advice so far as not using sulphite of soda, when so many found it a great assistance. One maker recommended its not being used.

Mr. BRIGHTMAN stated that, although he did not mean that it *always* caused "green fog," still sulphite of soda did so undoubtedly with some makes of plates; and he was so convinced of this in the case of some plates he had used, that when developing a batch not long since he cut plates in half before development and dodged the other plates about, using sulphite of soda with some and not with others, and found most conclusively that in the case of those developed with that salt "green fog" was most apparent to a greater or less degree.

The CHAIRMAN recommended the treatment of the sulphite of soda as recommended by Mr. T. Furnell, and which he had found a perfect preventive of evil results.

Mr. PHILLIPS asked if anyone present had experienced the extraordinary opalescent appearance which was seen on the surface of a negative during development, sometimes appearing like the top of a river where a freshly-tarred barge has passed along.

Mr. DANIEL said he had often seen it, and found that the effect on the film was to "tan" it and make it very horny. He had discovered it more often when a plate had had ammonia and pyro. added somewhat largely during development, and had been immersed therein for a rather long period.

After some further discussion a vote of thanks, on the motion of Mr. BRIGHTMAN, seconded by Mr. PHILLIPS, was unanimously accorded to Colonel Playfair for his interesting paper, after which the meeting was adjourned till the 26th instant.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

THE ninth ordinary meeting of this Association was held in the Religious Institution Rooms, on Thursday, the 21st ultimo,—Mr. John Parker, Vice-President, in the chair. The minutes of last meeting having been read and approved of,

The CHAIRMAN called upon Mr. Andrew Duthie to reopen the discussion on *The Cause of Fading in Silver Prints*, which had been left unfinished at the last meeting.

Mr. DUTHIE said:—The subject for discussion this evening is one of such importance that I would have been glad to have seen it in the hands of some one with much greater experience than myself—some one who would, therefore, be better able to handle it as it deserved. However, if unable to actually solve the question, I trust at least to show some reasons for the fading of silver prints. It is usually said that insufficient washing after fixing is the cause of fading, but this I am not prepared to admit, especially as we find unmounted prints by our best photographers are all liable to the same discolouration as mounted portraits. With those firms who deal largely in scrap photographs the washing receives special attention. Messrs. Wilson, for example, finish the washing in nearly boiling water. This would ensure the removal of the last trace of hypo. In 1849 Sir John Herschel recommended dabbing the back and front of the print with a soft sponge. This is to be repeated three or four times. He said if the washing was properly carried out photographers would be troubled no more by fading of prints. Of course the photographs he referred to were on plain paper, such as Whatman's drawing-paper. Nearly all of us, I think, have seen the books of calotype photographs exhibited by the Secretary at our last *conversazione*. They seem to bear out Sir John Herschel's statement, for they show no signs of fading. These are also on plain paper. This, I think, brings us a point nearer a solution of the difficulty. From what I have heard about prints on plain paper, and some experiments I have been making lately, I am inclined to think fading is, to a great extent, due to the decomposition of the albumen. I mentioned this the other day to a manufacturer of albumenised paper, and was assured that they treated the paper somehow with an acid to prevent decomposition taking place. If I am not mistaken it is citric acid that is used. This is very likely—indeed, almost sure—to be washed out by the time the print is finished. The albumen is, therefore, left without any preservative, and is a substance which would very likely succumb to the influence of a damp atmosphere or a hot sun. This seems probable, as we often hear of prints hanging on the walls for fifteen or twenty years and showing little signs of fading. All these years they have been pressed close to the glass of the frame, which is rendered nearly air-tight by being pasted over the back with brown paper. In the old frames the paper was only put round over the tacks, and this, I think, was more completely air-tight than the present mode of stretching it right across the back. I regret that the month which has elapsed since I undertook this subject has been too short to allow me to complete my experiments. I trust, however, towards the end of the year to have something to show in support of my opinion about the albumen. We shall now consider another cause of fading, which is not, I think, generally known. On inquiry I learn that hundreds of tons of hypo. are annually used by paper manufacturers. In fact, a friend of mine was told by a member of one of the largest firms that it was impossible to do without hypo. Napoleon I. once said that there was no such thing as an impossibility; still the paper makers seem to find one here. I mentioned at the last meeting some of the results I had got with about sixteen faded cabinet portraits with which I had provided myself. I omitted to state that they were taken by the leading London photographers. They were all portraits of celebrities, and had been shown in our windows in Renfield-street. They were exposed to the full blaze of the sun all afternoon and to the effects of gas at night. Some of them had been in stock three or four months; others twelve months. In every case I found traces of hypo., and in several free sulphuric acid was present. Three mounts were analysed. The first contained in an aqueous solution hypo., sulphates, and starch. In an acid solution there were traces of iron and lime, a considerable quantity of potash, and a good deal of soda. In this mount there was no excess of acid. In an aqueous solution of the second were found faint traces of hypo., sulphates, and chlorine. In the ash were iron, lime, potash, soda, strontium, and alumina; also a considerable quantity of free sulphuric acid. The last—the only one which resisted all tests—was a black one. It was free from hypo. and sulphates, although subjected to more severe tests than any of the others. It was neutral to test paper. I might also mention that I have tested a number of sample mounts belonging to various London and local dealers. I found that they all contained the same impurities, although varying in quantity. Before sitting down I would like to ask some of those present for their experience of gold bevelled-edged cards. There seems to be something in the colouring matter of the chocolate which is almost fatal to silver prints. The black mounts are the same, though in a less degree. The gum alone does not seem to injure the prints. In one case I had a *carte* photograph which faded so completely that the faces were flat and pale—so much so as to be unfit for use. All this took place in about three weeks. It was mounted on a chocolate card. In conclusion: I may just mention that white and yellow cards appeared to contain most free acid, while those of darker colours were mostly neutral to litmus paper.

An interesting discussion followed, and the meeting terminated with a vote of thanks to Mr. Duthie and the Chairman.

COVENTRY AND MIDLAND PHOTOGRAPHIC SOCIETY.

THE ordinary monthly meeting of this Society was held at the Coventry Dispensary,—Mr. Danks in the chair. After the usual business,

The Chairman called upon Mr. Arthur Seymour to read his paper on *Old Dry-Plate Processes*.

Mr. SEYMOUR said he began photography about the year 1858 by the successful dry-plate process of Fothergill, which was first introduced on the 18th May in that year. He then went on to speak of the troubles of a beginner, &c., and gave a general description of the process. A strong neutral silver bath, an old collodion, a careful washing, and extreme cleanliness seemed to be the chief points upon which success depended. The developer he used was the pyro.-acetic, with the addition of a few drops of a weak solution of nitrate of silver. The exposure in a fair light was from two to three minutes, and Mr. Seymour spoke feelingly of the bygone pleasure of seeing the image grow under the developer—a pleasure which is lost in the newer gelatine process. He also showed some negatives taken on oxymel plates, and also some on the meta-gelatine plates of Dr. Hill

Norris, which were much admired. He regretted he could not stay longer that evening having another appointment, and apologised for leaving so early.

A vote of thanks was unanimously passed to Mr. Seymour for his interesting paper.

The SECRETARY then asked each member present to accept a box of Mr. S. J. Lloyd's new mountant, whose qualities for sticking, keeping, &c., were known by several members present to be excellent. He also handed round some German sensitised paper for trial.

Mr. H. MOUNTFORT said he could recommend chloride of iron for reducing over-printed proofs (to be used after toning and fixing).

The meeting adjourned in the usual manner about ten o'clock.

LOCHEE PHOTOGRAPHIC CLUB.

ON the 29th ultimo, the Lochee Photographic Club held their first annual exhibition and *conversazione* in the Victoria Hall. The room was elegantly set off for the occasion, the platform being fitted up with all the draperies and machinery of a stage, in a most complete and effective manner. The walls were hung with a variety of specimens of the work of the members of the Club, including portraits, from the ordinary *carte* to the "life size" picture, many of them being splendid specimens of the art, both for minute accuracy of likeness and artistic pose and finish. The landscapes were numerous and formed a fine collection.

BAILIE OGILVIE, the President of the Club, presided, and, in opening the proceedings, said that the Club, whose first annual *conversazione* they were holding that night, was only originated in April last year, and although their existence had been but brief, still there had been diligent and persevering application to work, with what effect the audience could judge from the examples hanging around them. The Bailie then gave a *resumé* of the history of photography from its invention, forty-five years ago, by M. Daguerre, tracing its gradual but rapid development from then till now.

During the evening a number of photographs was shown by means of the magic lantern, which were much admired. A select programme of music was gone through by several accomplished amateurs. A dramatic sketch, entitled "Photographers in a Fix," was performed by members of the Club. The piece was capitally got up, and the various characters were delineated with marked ability and success. The performance excited most exuberant merriment among the audience, and proved thoroughly enjoyable. The whole entertainment passed off with the greatest *eclât*.

Correspondence.

DARK-ROOM ILLUMINATION.

To the EDITORS.

GENTLEMEN,—After the exhaustive correspondence and discussions on the subject of colour medium for illuminating the dark room, it seems to me time to inquire what practical conclusions may be drawn from the recent investigations. Experimentalists seem pretty well agreed that we may safely, and with advantage to our eyes, discard the ruby medium, and that yellow alone, or with the addition of green, is now recognised as "the happy medium."

I agree with one of your correspondents who considers that the safest colour for a medium should be the *complementary* of that which is most active in chemical force upon our sensitive plates. Admitting the latter to be violet, its complementary yellow, which is well represented in canary medium, should be all-sufficient as to quality; and so in practice it appears to be, where the quantity and direction of the light are properly regulated.

In my opinion Mr. H. S. Starnes is correct in advocating the practice of cutting off direct light and working by reflected light. I have long worked upon that principle, by setting up an opaque screen between the source of light and my developing dish, so that all the light falling upon the plate is weakened by reflection and diffusion. One may thus have abundance of light in the room, and yet controlled from doing mischief.

Those who develope by daylight require some arrangement capable of ready adjustment to the varying strength of the light outside. Even upon a window in an aspect free from sunlight the amount of light varies so much at different times and seasons that it requires a convenient means of control. To the amateur who has but one room for all operations the means of admitting more or less light according to circumstances is most important. To accomplish this end I would suggest having a frame to fit the window, or the upper portion of it, covered on the outer side with canary paper, mounted with rotating laths—in fact, a Venetian blind—so set that no direct light should pass through it, but be thrown upwards, with, if necessary, a yellow screen overhead to catch and reflect the light down again. The lower part of the frame for about a foot above the level of the developing-dish should be made opaque. The advantage of such an arrangement is that the amount of light would be under control by opening or closing the apertures, and, when more light is required for the subsequent operations, it may be instantly secured by reversing the laths.

With these few hints to all whom they may concern I must leave each operator to adapt the details of arrangement to his own special conditions and requirements.—I am, yours, &c., G. S. PENNY.

Cheltenham, March 3, 1884.

SODIC SULPHITE.

To the EDITORS.

GENTLEMEN,—"Free Lance" says he gets a stain on his fingers notwithstanding the use of sodic sulphite. I am glad to have his countenance in its use; but really if he used an old kitchen or pocket knife to raise up his plates for inspection he need not soil them. Fortunately the stain is readily removed. Let him add a few drops of acid—either hydrochloric or sulphuric—to a little water, or put in a few crystals of citric acid until acidulation is produced, and on dipping the fingers in and rubbing it over the stains will disappear.

I have already said I differ totally from Mr. B. J. Edwards on his assertion that inferior pictures are produced by sodic sulphite. Had this been so, it would have been found out and commented on before now. So far is this from being the case, that pictures of the most exquisite qualities are produced rapidly by persons who would at once give it up if quality were lacking. I have only found one make of plate unsuited to it after trying almost all known brands.

On the question of whether sodic sulphite does or does not preserve the developer clear and prevent the usual muddy precipitate, any one can test it by pouring into a glass measure for examination the fluid used in developing. I should not have conceived it possible to call it in question.—I am, yours, &c., SAMUEL FRY.

Kingston-on-Thames, March 4, 1884.

To the EDITORS.

GENTLEMEN,—I should be glad to learn the best way to mix the sulphite of soda so as to make up a stock solution after the manner of Edwards's formula. Mr. H. B. Berkeley says:—"Mix the citric acid in water, then the sulphite of soda, and add to the pyro."

To make up a stock solution I dissolved sixty grains of citric acid in seven ounces of boiling distilled water, then two ounces of sulphite of soda, and when cool enough I poured it into a one-ounce bottle of pyro.; but by the time I had used one half of it the rest had become discoloured almost like claret. Is there any remedy for this?

As regards the amount of citric acid used to preserve the pyrogallic *without sulphite*: it seemed to me that the negatives were more brilliant with a full dose of the acid. Of course as little as twenty grains will preserve an ounce of pyro. a reasonable time; but are the resulting negatives as good? I think not. Perhaps Mr. A. Cowan might have something to say on this matter. His opinion would at least be valued by—Yours, &c., H. W. B.

Edinburgh, March 3, 1884.

LANTERN SLIDES.

To the EDITORS.

GENTLEMEN,—In your report of the last meeting of the Photographic Society I am credited with having shown some slides prepared with "*wet collodion.*" The statement is a little unfortunate, as the slides in question were upon slow commercial gelatino-bromide plates; and the only object I had in exhibiting them was to show what results could be obtained with these convenient materials even by unskilled hands.

The subject is well worth further experiments; for, as a rule, negatives taken by amateurs will not permit them to use direct contact printing with the great advantages this offers. A great number of gelatine bromide slides were passed through the lanterns last Tuesday; and, so far as I could judge, they would fully meet the requirements of an amateur. When thrown on the screen these pictures were very clear, soft, and vigorous, and of a warm black colour; but it was proved that a great range of tints could be obtained by altering the developer.

My own specimens were reduced from whole-plate negatives by camera with artificial light; and from a good negative it is easy to secure absolutely clear lights and a warm black transparency. I found it necessary to give a full exposure, and to use a rapid developer (sulpho-pyrogallol), followed by Cowell's clearing solution and a final rinse in dilute nitric acid.

No doubt, much depends upon the plate. I have tried four lots, but can only get good results from those by one particular maker.—I am, yours, &c., H. A. MONCRIEFF.

March 4, 1884.

SINGULAR LUMINOSITY OF THE ARGENTIC-BROMIDE GELATINE FILM.

To the EDITORS.

GENTLEMEN,—Allow me to point out to Mr. H. H. Cunningham the probability that the greenish-blue light he refers to is nothing more than the *complementary colour* of his two thicknesses of orange-coloured paper produced on the retina of the eye.—I am, yours, &c., A. S.

March 3, 1884.

BIRMINGHAM AND MIDLAND INSTITUTE SCIENTIFIC SOCIETY: PHOTOGRAPHIC SECTION.

To the EDITORS.

GENTLEMEN,—I beg to inform those correspondents who have been inquiring for a photographic society for Birmingham that the Birmingham and Midland Institute Scientific Society has a photographic section open to all persons connected with the Institute, and, therefore, at a nominal cost to anyone interested.—I am, yours, &c., C. J. WATSON.

34, *Smallbrook-street, Birmingham, February* 29, 1884.

GREEN FOG.

To the EDITORS.

GENTLEMEN,—A very singular fact in connection with green fog in gelatine plates came under my notice a few days since, which, being quite beyond my comprehension, I will, with your permission, briefly describe in the Journal, as it may tend, perhaps, to throw some light on this unwelcome phenomenon.

I was asked, on going into a professional friend's studio, to look at some negatives that he had lately taken on some plates of his own make, and developed with alkaline pyro. I at once said—"Well, there is, certainly, plenty of green about them." "Yes," replied he; "but look at the portion about the middle, on which the plate rested on the pneumatic holder while they were being coated." And, lo! *not a sign of it there!* He will be very happy to send you up one or two of the negatives if you would wish to see them.

Will some of my more experienced brethren kindly explain this?—I am, yours, &c., HENRY B. HARE.

Great Elm Rectory, February 28, 1881.

[We shall be interested in seeing a specimen of this curious phenomenon.—EDS.]

"FREE LANCE" AND PHOTOGRAPHIC PERSPECTIVE.

To the EDITORS.

GENTLEMEN,—In reply to "Free Lance," in your issue of February 29th, permit me to thank him most cordially for his good opinion of my lecture, *Camera Lucida*, &c., and also to own my mistake regarding that misleading passage to which he refers. The fact is that I was mislead through seeing so many photographs out of perspective as regards the lines of buildings—objects thrust too close to the camera, &c.

Since writing my lecture I have seen instruments which correct all these errors, and also some expedients. These I thought impossible in the art of photography, which increase my wonder and speculation as to the future of the science, so convinced am I that we are but at the gateway of photographic discovery and utility.

Tonight, when coming home, a botanical friend informed me that he has been taking some microscopic specimens with the camera, thus:—He unscrews the ordinary lens and inserts his microscopic glass instead. In this way he is able to make photographic enlargements direct from nature. Before long we shall hear of some great spirit discovering the art of photographing the *blues* in nature with the *browns*, and this will be the "beginning of the end."

Again thanking "Free Lance,"—I am, yours, &c.,

72, Princes-street, Edinburgh, March 3, 1884. HUME NISBET.

To the EDITORS.

GENTLEMEN,—In your last issue "Free Lance" criticises Mr. Hume Nisbet's paper in your Journal of January 18, 1884, but he did not explain how far his ("Free Lance's") picture was to be from the eye to cover the whole of the landscape or part. I suppose that the focal distance of the lens which he used for his picture and the axis of both picture and landscape are what he means when he talks of exact superposition.

The foot-note of Mr. Nisbet is, I consider, perfectly illogical, inasmuch as he states:—"The photograph is most to be relied upon for truth in all except perspective;" that is to say, that the smaller details are useful to him.

Now, if the perspective of the *whole* be defective, it is very evident that the perspective of the *smaller parts* will suffer proportionately; and it is a pity that an artist should lose himself by copying such, as they would only teach him to err.—I am, yours, &c., COLESWEGEN.

March 4, 1884.

Notes and Queries.

NEGATIVE wishes to know how to make negative varnish by the aid of white hard spirit varnish. Let him dilute it with an equal volume of strong alcohol, and add two or three drops of castor oil per ounce.

I WANT information as to the tariff or duty on the importation of dry plates in America; also relative cost of plates and general materials in America compared with Britain; and, lastly, whether English plates are used there.—R. CAMERON, Maryhall-street, Kirkcaldy.

H. RICKETTS desires to know if a certain card mount (a specimen of which he encloses) is likely to cause a print to fade. We think not. He also inquires why the burnisher leaves a mark in one place more than another. This arises from his having made a temporary stoppage at the place in question.

G. O. MARR sends us a list of views of Westminster Abbey and other public buildings in London which he would like to obtain if he knew to whom to apply for the same. This list also includes a view of Dover from Folkestone. Had he not better specify his wants in our advertising columns, giving his name and address? He would meet with many responses.

WILL some experienced photographer kindly advise me as to the best way to pay a landscape operator; also a fair salary for a good one? I also want to know the best way to heat a printing and storing room, with work-room above, which I am building; and a good way to arrange the printing-room which is a large one. Also the best and easiest way to name and number landscape negatives, to show well on the prints.—A BEGINNER.

T. D. says:—Will you kindly inform me of the best publication on retouching and enlarging for amateurs, and oblige?——In reply: Let "T. D." consult our ALMANAC for 1878, and in it he will find a series of chapters entitled *The Modern Practice of Enlarging*, in which is given all the necessary information. As regards the subject of "retouching," we shall have to refer him to the previous volumes of this Journal, there being no work at present in the market devoted to it. A treatise by Burrows and Colton was the last that was published, and although out of print, in the commercial sense of the term, a spare copy may possibly still be had at some of the dealers in photographic materials and literature.

G. B. inquires by what means he can get his customers brought into the habit of paying when giving their orders.——In reply: Let him place a printed announcement in his reception-room that on and after the first of next month (April although it be) no portrait will be taken unless upon the presentation of the receipt for the amount of the order to the superintendent of the operating-room.

WOULD you kindly inform me of the nature of the velvet roller used and exhibited by Mr. T. Bolas, F.C.S., in his recent lecture on *Photo-Mechanical Printing?*—1. Whether an ordinary lithographic roller covered over with velvet would do, or must it be a specially-prepared kind of roller, and if they can be had commercially?—2. Having procured a velvet roller, is the roller manipulated in the same way as the lithographic one, namely, rolled up in litho. greasy ink, and then passed over the exposed gelatine print; that is, was it simply by substituting a velvet roller for a lithographic one that the great difference between the two transfers was produced?—TRANSFERER.——Will some "expert" kindly answer these queries?

IN your next issue can you tell me how to prepare, and what medium to use, in colouring photographs? In using water colours the paint rubs off; besides, it is very difficult to get on. I have tried gum water, but on large surfaces it does not answer, and in oils I am anything but successful. Any information, with name of a work on photographic painting, will greatly oblige—W. C. HARRIS.——In reply: When water colour does not readily "take" to the surface of an albumenised print, the simple expedient of applying the tongue to the surface will effect a union. But the leading manufacturers of water colours supply prepared ox-gall, specially intended for such a purpose. We have seen a "medium" which was very useful for mixing with water colours, but have a strong idea it was composed in a large measure of ox-gall.

I HAVE a 10 × 8 rapid rectilinear lens, by Dallmeyer, and a 9 × 7 portable symmetrical, by Ross. By using a small stop would either of the above cover a plate 15 × 12? I also have a Ross' No. 3 cabinet portrait lens. Which would you prefer for taking cabinets or large heads in the studio? I find the Ross' portable very slow for studio work.—S. J. B.——In reply: The Ross' "portable" is not intended or adapted for the purpose mentioned. For cabinet portraits in the studio the cabinet lens is preferable to any others. For large heads either the rapid rectilinear or the front lens of the cabinet objective may be employed. Either of the two first lenses specified by "S. J. B." will cover a 15 × 12 plate, provided the front or back lenses alone are employed. For ascertaining the circumstances under which they do so, we must refer him to a series of articles on the *Optics of Photography and Photographic Lenses*, in our last volume.

E. J. says:—Last summer I attempted a large number of instantaneous photographs of cabinet size, with a single landscape lens of ten inches focus and George Smith's blind shutter. These views included persons walking. Three views out of four failed. If the shutter were worked quickly the negatives fogged over before the details were out. When the shutter was worked less quickly the figures were blurred. I have a new Ross' "universal" lens of ten inches equivalent focus which I propose to have fitted up with ——'s new shutter, for use on the same class of view; but before purchasing this shutter I beg leave to ask you whether any other shutter would be preferable, and whether (having the "universal") it would be worth my while to buy at the same time any other form of lens.—E. J. W.——In reply: The negatives having fogged when the shutters was worked quickly merely indicates that "E. J. W." had not acquired a mastery over the best method of developing the negatives, and he must subject himself to a course of education to prevent the recurrence of this. The "universal" lens named is capable of giving a well-exposed negative with any (even the quickest-acting) shutter at present procurable. We assume, of course, that the subject is an outdoor one, and that the light is good.

If "Inquirer," in last week's Journal, will apply a paper knife to his prints, giving them a slight curl in the direction opposite to that at which they are now, he will get his prints to remain sufficiently flat. If he desire a polish, why not surface the prints with collodion and gelatine according to the glacé process?—F. R.

Exchange Column.

No charge is made for inserting these announcements; but in no case do we insert any article merely OFFERED FOR SALE, *that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a* NOM DE PLUME *be thought desirable), otherwise the notice will not appear.*

I will exchange good English gold and other frames for good photographic apparatus.—Address, JOHN LEWIS, Gladstone-road, Sparkbrook, Birmingham.

I will exchange a tripod stand, whole-plate camera, sliding-body, and portrait lens, by Jamin, for whole-plate bellows-body camera, in perfect order.—Address, WALLACE FIDLER, artist and photographer, Cavendish-street, Chesterfield.

I will exchange an 8½ × 6½ camera, for cabinets and *cartes*, by Ottewill, a 10 × 8 ditto, a landscape lens, for 12 × 10 and upwards, by Grubb, THE BRITISH JOURNAL OF PHOTOGRAPHY and the *Photographic News* for the past year, 1,000 *carte* mounts enamelled and gilt edged, a silver watch, gold studs, and a lot of rare postage stamps, for a good second-hand lens, or anything useful.—Address, E. G. G., Sherwood Villa, New Southgate, N.

Wanted, Ross's portable symmetrical, No. 3, in exchange for a capital whole-plate portrait lens, with rack and pinion.—Address, PHOTOGRAPHER, Cambray Studio, Cheltenham.

I will exchange an English concertina, forty-eight keys, in rosewood lock-up case, perfect order, splendid toned violin, gentleman's silver Geneva watch, quite new, warranted in perfect order. Wanted, a 15 × 12 camera, Kinnear or other good maker, suitable for dry-plate work, with double slides, folding tripod stand for whole-plate Kinnear camera, backgrounds, or other useful accessories.—Address, J. B. SMITHSON, Leyburn, Yorkshire.

What offers for THE BRITISH JOURNAL OF PHOTOGRAPHY, from January, 1877, to December, 1883, clean and perfect, about half a ream of white Saxe albumenised paper, four pints Sœhneé negative varnish, and quarter-plate walnut camera with lens, fitted with Waterhouse's stops? Wanted, $8\frac{1}{2} \times 6\frac{1}{2}$ or 10 × 8 camera, in good condition, with sliding-body preferred, and good cabinet lens.—Address, G. H. E. SUTTON, 47, Crown-street, Bluebell-hill, Nottingham.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

PHOTOGRAPHS REGISTERED.—

William Child, photographer, 14, Wellington-street, Leeds. — *Three Photographs, of John Barran, Esq., M.P. for Leeds.*

John Horsburgh, 131, Princes-street, Edinburgh.—*Four Photographs of Mr. John Bannister as Lord Beaconsfield and Mr. Gladstone.*

John Yeoman, The Villas, Bedale, Yorks.—*Photograph of an Address Presented to the Marquis of Carmarthen on his Marriage with Lady Catherine P. Lambton.*

NOTICE.—*Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a* NOM DE PLUME *as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.*

WILLIAM.—We have not lost sight of the matter. All in good time.

F. EVANS.—Warnerke's standard sensitometer is supplied by Messrs. Marion and Co., Soho-square, W.

A DEVONSHIRE AMATEUR.—Any camera-maker will supply the necessary appliances. The cost will probably not exceed a couple of pounds. The apparatus is not patented.

G. B. BLIGHT.—Your best plan, for the small quantity you require, will be to purchase the indian ink in the fluid form. This you will be able to do from any artists' colourman.

NEMESIS.—Certainly, you *can* make gelatine from parchment cuttings; but we fear that it will not be worth your while to manufacture it in that way for emulsion-making.

A. S. YEOMAN.—You evidently take far too desponding a view of the situation. Bear in mind that "there are as good fish in the sea as ever were caught." Take heart and persevere.

ARTIST.—The most—indeed the only—satisfactory method of producing photographs on ivory is by the carbon process, which is by double transfer from a flexible support. You will not succeed, we fear, by silver printing.

SALOP.—There is little wonder that you cannot get fully-exposed "instantaneous pictures" with the "rapid lens" if you stop it down to the extent you have done. To succeed, you must employ the full, or very nearly full, aperture.

WILLIAM MILLER.—Yes; you will, practically, get better instantaneous pictures with the larger of the two lenses, inasmuch as on the size of plate you are working you will be enabled to employ a larger aperture; consequently, in practice, you will be able to work quicker and yet get good definition over all portions of the picture.

IMPROVER.—Your best plan will be to advertise for an appointment as assistant operator in some good house. If you can show some moderately-good work of your own we do not think the fact of your now being engaged in a third-rate studio will be any drawback to your securing employment as assistant in a first-class house.

B. C. A.—If the stains cannot be removed by either of the methods you have tried the opal glass must be reground. This is not a difficult matter. Procure some *fine* graining sand from a lithographic printers' material dealer. Sprinkle a little of this on the opal, wet it with water, and then grind it, using a small piece of plate glass as a muller.

E. BEVERIDGE.—No. 1 on your list will be the most rapid of the three, and, if you wish to take instantaneous views as well as landscapes, certainly it will be the most generally useful. For the size of plate you are working upon, and taking into consideration the lenses you already possess, the shortest focus (the thirteen-inch) will answer your requirements. For a sixteen-inch focus lens for pure landscape work one of the lenses in the eight-inch "rapid" will answer well if stopped down.

R. S. J.—You are, in our opinion, decidedly in the wrong. You are apprenticed to learn the business of a photographer. Surely cleaning glass, even if old negatives, is something that you require to learn; so also is mounting and rolling prints. All this is legitimate, and you certainly are not justified, in the eye of the law, in refusing to carry out your employer's instructions in these matters. If he were to take you before a magistrate for refusing to do your work you would find yourself in a very unpleasant position.

CHAS. G. WILLIAMS.—What kind of surface do you wish to sensitise? How is it possible for us to answer such a query as "how to sensitise a surface" without knowing more of your requirements?

C. A. BREWSTER.—The views are very good, but nothing at all extraordinary, as you appear to imagine. When you have had more experience we shall not be surprised if you are not so proud of them as now.

MABLE.—All will depend upon circumstances. In some cases it is better to purchase a business; but, if you are a good business man as well as a good photographer, it might possibly answer your purpose to commence a new business rather than purchase an old one. You must, however, bear in mind that to start a new concern in the modern style will, with the construction of the studio, involve a considerable amount of capital. Added to this you must be prepared at first to lose some money, as the profits cannot be expected to flow in from the commencement.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 12th, inst., the subject for discussion will be—*On Dark Room Illumination.*

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The next meeting of this Society will be held on Tuesday next, the 11th instant, at 8 p.m., at the Gallery, 5A, Pall Mall East, when a paper on *Illumination of the Dark Room* will be read by Captain Abney, R.E., F.R.S.

CALCUTTA EXHIBITION.—A cable message has been received intimating that a gold medal has been awarded to Mr. J. H. Steward, optician to the Government, 406, Strand, London, for his exhibits of triple and biunial lanterns, telescopes, field glasses, and scientific instruments.

LONDON GAZETTE, *Friday, February* 29, 1884.

SCOTCH SEQUESTRATION.

ALEXANDER SIMPSON AND THOMAS HARIOAD DOUGLAS, trading as Simpson and Co., 34, Constitution-street, Leith, photographers.

Tuesday, March 4, 1884.

PARTNERSHIP DISSOLVED.

ALFRED EDWARD FOX, JOSEPH WALTER BUSH, AND CHRISTOPHER FOX, trading as Fox, Bush, and Fox, Commercial-buildings, Bridge-street, Bradford, and 123, Witham-street, Kingston-upon-Hull, photographers and portrait painters.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician,
For three Weeks ending March 5, 1884.
THESE OBSERVATIONS ARE TAKEN AT 8.30 A.M.

JOURNAL OF PHOTOGRAPHY.

No. 1245. Vol. XXXI.—MARCH 14, 1884.

A NEW METHOD OF KEEPING EMULSION.

Circumstances very frequently arise under which it is desirable to make a considerable quantity of emulsion which cannot be used up at once. We speak now more especially of amateur practice, though the same argument will hold good with professional photographers who may prefer to make their own plates.

In order to secure uniformity in sensitiveness and other qualities it has been a practice, in many cases, to mix together several small batches of emulsion, and so "average" the qualities—good and bad—of all. But in proceeding on these lines a difficulty arises in the fact that, though the mixture of numerous samples of emulsion, when newly put together, may represent uniformity of character in its best degree, still that mixture must be spread upon glass and dried as soon as possible in order to utilise to the full the advantages of uniformity. In other words, the emulsion must be used up at once in order to avoid decomposition, partial or total, and alteration in sensitiveness, both of which may accrue from keeping.

The trouble involved in the operation of drying emulsion in order to make it into "pellicle"—as it has been called in the dry state—is sufficiently great to deter many or most small consumers from adopting that plan, which otherwise seems to offer a fair chance of securing absolute uniformity in different portions of the same bulk of emulsion, though they may be used at widely-different intervals of time.

The conversion of emulsion into pellicle for the purpose of commercial supply is a branch of the dry-plate maker's business which is, to our mind, greatly and unwisely neglected. Very many—both amateurs and professionals—who now decline to use "bought plates" would not hesitate to adopt a commercial emulsion if it could be placed before them in a practical form. Many and loud are the complaints which reach *us* of trivial faults in this or that maker's plates—faults which the complainants themselves acknowledge are only mechanical and not in any way connected with the emulsion itself. Bad quality of glass is the most general complaint. Inequality, irregularity, or absolute incorrectness in cutting to size is another; and defective packing arrangements and many others form a tolerably long list of faults which are beyond the control of the consumer, who would be glad in many cases that have actually come under our notice to continue using the *films* to which he has become accustomed, and found satisfactory in quality, if they were only supplied to him in a usable form—that is, on good glass and cut to proper size.

This or these difficulties would be quite met if dry-plate manufacturers would supply a guaranteed emulsion — such as they themselves employ in their own practice—in such a form that, while it has keeping qualities, it is ready at any moment for the photographer himself to apply to whatever quality of glass he may choose to employ and in any fashion. Such a system would be an actual advantage to the plate-maker, inasmuch as, provided the emulsion be all right, he will be absolved of all mechanical sins.

It is possible, however, on the smallest scale, to prepare an emulsion which will keep for any reasonable time, and thus dispense with the aid of the professional plate-maker if he decline to adopt the system; indeed, if amateurs could only, by (as it were) making "one bite at the cherry," get over the difficulty of preparing emulsion for a season's work with one expenditure of trouble and upsetting of ordinary arrangements, there would be many more amateur plate-makers than there are at present. The method we propose describing in brief will enable this to be done on either the small or large scale.

Everybody nowadays is familiar with the famous (or infamous) "graph" printing surfaces, composed simply of gelatine and glycerine. Most of us if not intimate at the present day at least remember at some period of our existence the form of confection known as "jujubes," which will be also found to be composed mainly of gelatine, sugar, and glycerine. Now, neither of these preparations—the chromograph mixture or the jujube—shows the slightest tendency to decomposition or loss of strength in the gelatine, however long they may be kept; hence we may calculate that the preservative action of the glycerine and saccharine matter is worth consideration from a photographic point of view.

As a matter of fact—led in that direction by the ideas given above—we have been experimenting with an emulsion for keeping purposes with results that we venture to think will commend the process to many more than those who merely want to save trouble in the preparation of their plates. There are many possible applications of the principle or principles involved, but we shall deal only with one in the present article, namely, the preparation of a "keeping" emulsion in a portable form.

This preparation, whatever may be the actual shape in which it is finally moulded, is practically a "chromograph" mixture *plus* bromide of silver; that is to say, a mixture of gelatine, glycerine, and bromide of silver, with as small a quantity of water as possible.

The sensitive salt is formed by one or other of the "precipitation" methods. We do not recommend any special one, all being equally applicable. The bromide, having been prepared in a fine state of division and washed free of all soluble matter, is mixed with the gelatine and glycium, so as to form a very strong jelly (if the form in which we are accustomed to find jujubes can be called "jelly"), in which state the preservative or antiseptic action of the glycerine will suffice to render the preparation practically indestructible.

Here is a formula briefly given, as we shall have to return to the subject in different phases subsequently:—

Silver nitrate	480 grains.
Potassium bromide	360 „

Mix and precipitate by any of the well-known methods. To the precipitated bromide thus obtained add—

Gelatine	1 ounce.
Glycerine	1 „
Water	2 ounces.
Alcohol	1 ounce.
Salicylic acid	5 grains.

Shred the gelatine very finely, and throw it into the vessel containing the silver bromide. Mix the glycerine and water, pour into the same vessel, and allow to soak, stirring at intervals in order to bring every portion of the gelatine into contact with the aqueous glycerine. After an hour or two apply heat, and liquefy with constant stirring in order to render the mixture homogeneous. When all the gelatine is dissolved and the bromide equally spread throughout the solution heat the alcohol in a glass flask, and, having dissolved the salicylic acid therein, pour it gradually into the gelatino-bromide mixture, stirring vigorously for some time. Then allow the whole to "set," and the preparation is complete.

When quite cold this will be found to form a hard, solid mass, which presents a slight tackiness and may be handled with as little inconvenience or danger as if it were perfectly desiccated. The preservative action of the glycerine suffices to keep it for practically any length of time, and it is ready for use in a very short period when required.

The method of use and other applications we must postpone until next week; meanwhile we can fully recommend our readers to try this method in view of the approaching season.

THE PHOTOGRAPHIC USES OF A NICOL PRISM.

In an article in our last issue, on *Polarised Light*, we spoke of a bundle of nine or ten glass plates as the most effective source of polarisation, when the object to be attained is the projection of crystalline or other structures on the screen by means of the lantern.

It will readily be understood, however, that the formation of an image, when such an obstacle is interposed in the path between the object itself and the objective, will be, practically, impossible, on account of the great number of reflections and refractions to which it is necessarily subjected by a series of transmissions through nine plates almost indefinitely multiplied. For this reason, although the bundle answers quite well for polarising a beam of light, it cannot be admitted as a factor in the transmission of those rays which are *en route* towards the formation of an image, or as part of an optical system engaged in such formation.

This will be well understood from the following:—Let a bundle of nine plates be interposed at the polarising angle between the eye and any well-lighted object of a marked character, and it will be found that, apart altogether from the loss of light sustained, distinct vision cannot be obtained.

Quite contrary to this is the nature of the image observed when employing the Nicol prism as a means of observation. No displacement and consequent confusion are created by its agency, and hence it may be fittingly interposed between an object and its image without affecting the formation of the latter, except as regards the polarisation of the rays by which it is formed. It thus becomes, in the present state of our knowledge of the properties of substances, the most perfect means by which photography is capable of being employed in connection with polarised light. We may here state that the included angle in all photographs of the character under consideration is necessarily very small. Although subject, however, to this drawback, they possess a utility difficult to over-estimate. A few of the services capable of being rendered to photography by the Nicol prism will now be described.

In referring to the means by which certain classes of foliage may be photographed we may, first of all, direct attention to the fact that when looking upon a mass of foliage having smooth, shining leaves, which reflect light freely, this tendency is found to predominate to such an extent that all attempts to photograph them result only in total failure in representing them as they really exist. The photograph will show them as if the leaves were covered with snow. Now look at them through a Nicol prism, and rotate it slowly until the polarised rays reflected from the leaves are stopped by or absorbed in the prism, and then the glitter and the reflection are lost, and the surfaces of the leaves become as if formed of green velvet, the other portions of the vegetable structure undergoing no change.

To apply this to the photographic lens: the best form of objective to which we have yet attached a prism is the ordinary landscape combination, consisting of a single achromatic plano-convex or meniscus lens, having a diaphragm in front and a tubular projection in front of the diaphragm in which to insert the prism, the fittings sufficiently loose to permit of the prism being easily rotated. The prism must be large—certainly of larger dimensions than the diaphragm. Having focussed the foliage, rotate the prism until the reflected light from the leaves has been depolarised, and then let the exposure be made. For purposes of comparison a second negative should be taken immediately afterwards without depolarising the light. The difference between the two will be found most marked.

The glare reflected from the surface of water will, under most conditions, be found to consist of polarised light. We need scarcely remark that under certain circumstances, when walking by the side of a stream from which light is brightly reflected, it is impossible, because of this reflection, to see not only the bottom but, even below the surface to any extent whatever. Now let the services of the Nicol prism be utilised as an eyepiece (we may here say that this prism neither magnifies nor diminishes the object examined), and upon rotating it slowly, as before, a point is reached at which the reflected light becomes extinct, and the surface of the water no longer forms a barrier to the investigation of the contents of the water and of the bottom. Fish, where present, along with other objects previously quite invisible, are plainly seen through the pellucid water now deprived of the power of interposing its reflections between the eyes of the observer and the treasures held in its depths. What the eye here distinguishes, that can the camera photograph under the circumstances of depolarisation described as being necessary in connection with foliage.

It is well known to all who are familiar with the phenomena of polarisation that the pure blue sky in the north, when viewed at a height of about 45°, radiates polarised light in rich profusion. If an examination be made by means of the Nicol prism this portion of the sky will appear dark to a degree more or less marked according to the special part examined and the rotatory position of the prism. Now repeat this examination when a small fleecy cloud (so feeble in its luminous radiations as to be scarcely visible) moves across that portion of the sky, and the curious phenomenon of a nearly pure white cloud upon a black ground is witnessed. We have here merely to repeat that what is thus discerned by the observer's eye may, by the means previously described, be delineated upon the sensitive photographic plate.

Not to speak of selenites and the numerous crystallisations which can be properly seen only by polarised light, there are innumerable objects in both the vegetable and animal kingdom which would defy the utmost skill of the scientist to photograph were he not aided by polarisation. Let him, by way of example, try to reproduce photographically, by means of ordinary light, a thin section of a rhinoceros' horn, a pellicle of the skin of an onion, a thin crystal of hyposulphite or carbonate of soda produced by evaporating upon glass a weak solution, sugar, hippuric acid, tartaric acid, silver nitrate, and other articles which could be enumerated by the hundred, and what a signal failure must he experience! These articles have form and richly-varied internal structure, but the eye of the most skilled observer and also the eye of the camera are blind to their beauties. Let but a ray of polarised light illumine them and instantly they undergo a change—not in their nature, but in their visibility. Their wonderful structure stands revealed, each portion in colour differing from another, their backgrounds being black, blue, red, green, purple, orange, or one of the many bright hues capable of being obtained by the agency of selenites. Any colour or ground may be produced at will without affecting the object itself, and this affords the photographer an opportunity of selecting that which contrasts best with the character of the object being photographed.

A SAFE LIGHT.

At one of the monthly technical meetings of the Photographic Society of Great Britain, when Mr. W. E. Debenham's exceedingly-interesting proposal that has of late been so much before photographers was under discussion, we noted a remark made by Mr. Payne Jennings which recent experiments strengthen us in believing to be as true as it was pithy. He said:—"I think that there is not any light which is perfectly safe; therefore, if a valuable negative is being developed, my advice would be not to go too near any light until the image is well out." The gist of the whole discussion is contained in the first part of the sentence, whatever views may be held as to its practical application in the latter half. We have lately been experimenting with a very large number of "safe" lights, and the results have uniformly shown that a safe light does not actually exist. We, of course, refer not to plates specially prepared to register the action of rays of low refrangibility, but to ordinary commercial dry plates, such as would be found in the dark room of any photographer in the kingdom. We unhesitatingly state that we have not yet tried a single one of the so-called "safe lights"—or, more particularly, we should say "light filterers"—which would fail to allow a plate to be acted upon if placed in the most suitable position to receive any actinic radiation, if such were present.

The subject is complicated by many side issues, which, after describing our experiments, we may treat in turn in the endeavour to indicate the practical conclusions that may be drawn from them.

That ruby glass alone is not a safe light has long ago been definitely testified; for the spectroscope proves that it allows some of the blue rays to pass, so that the old two thicknesses of ruby glass would simply slightly lessen the amount passed through. With regard to the effect of different layers of the same coloured light filterer, Mr. A. Cowan's experiments, as narrated in our pages last week, do but give a useful practical exemplification of a well-known fact. Thus Professor Tait, lecturing upon the subject of absorption, &c., says:—"If I take a number of pieces of glass, light which has passed through one of these is capable of passing in greater part or percentage through the next, and what has been sifted through two of them will in still greater percentage pass through the third, and so on." Thus Mr. Cowan proved that when yellow paper had performed its sifting functions upon the light a piece of glass of different colour had far more effective action than two extra thicknesses of paper, while before the light had been sifted it did not equal one sheet.

Our own experiments have been with a large number of aniline dyes, and they were designed so as to assimilate in practice the experience of those who work with artificial light. We tried to find not what was a safe-working distance, but what medium (if any) was safe at any distance. Our coloured screens were placed four inches from a No. 6 bat'swing burner, and gelatine plates of various types were used.

An opaque screen, provided with a small aperture having an arrangement for holding various pieces of coloured glass, was placed in front of the light. We may here say that for coating glass with dyes we found collodion, though giving so fragile a film, far preferable to varnish, as the latter had an unpleasant trick, when strongly coloured, of losing its cohesion and drying in clots—"sessing," as the painters term it. The gelatine plates were placed immediately in front of the flame and one inch from this aperture, which was provided with different glasses, obscured with paper, &c. Leaving on one side the results of the many other dyes we used we will confine our details to the effects of those made with aurine and roseine, they being well known and as effective as any.

It may be well to observe that in all cases we judged of the effect by placing a plate in an ordinary developer for an average length of time, and observed the effect *before* fixing, as a slight impression is more easily seen before than after fixing, and time also is saved.

Plain ruby glass gave a strong impression; double thickness a similar result. The same glass with one thickness of orange tissue paper was plainly impressed in one second; with two thicknesses also strong action was apparent. We then, leaving *in situ* the ruby glass and the two thicknesses of paper, placed a screen of aurine glass, and gave four, ten, and twenty seconds' exposure. The four seconds' exposure gave sufficient proof of action to have utterly ruined any negative.

Next, the paper was removed and ground glass substituted, when, as before, a "snap" exposure gave an impression. Not to make our details too wearisome, we may say we added successively to the screen of ruby and ground glass one screen of aurine, one of roseine, two of aurine, two of roseine, two of aurine, and one of roseine; two of roseine and one of aurine; two of aurine and two of roseine. The colour of the screens was very deep. In every case, if a plate were held before the aperture for such a length of time as an operator working by lamp- or gas-light might hold a negative to ascertain if a face (for example) were "sharp," the light acted sufficiently to produce a decided impression sufficient entirely to mar the brilliancy of a negative if developed out.

It will thus be seen that, so far as our experiments carry us, no screens obstructed all the actinic light, and that, therefore, a "safe" light was not given by them. In practice, however, the negative could never be developed in such a glare; and, if it were held up close to the light to examine it for sharpness or density, it would be nearer the conclusion of the development, when, if even any effect were produced, it would not be allowed to develope out, the negative itself being fully developed, perhaps, at the time when any light-stain produced would only be faintly indicated, if at all. The old idea that light will act slightly or not at all upon a plate wetted with the developing solution is entirely untenable (as anyone can ascertain in a moment by comparison), so that no immunity from fog, when using unsuitable light, can be expected on that account.

It is, therefore, obvious that when daylight is used the suitability, or the reverse, of a screen depends entirely upon the position of the window with regard to the light of the plate and to the window. On placing a gelatine plate (say) two feet from a gas flame it would be found that if ruby glass were placed on the negative it would be some minutes before a plate was impressed; but if the glass were placed almost close to the flame a few seconds only would be required. It is simply a question of the amount of light the plate received, and similar conditions prevail in daylight illumination.

Then, again, in fixing upon a safe light, even at a working distance from the flame, it must be remembered that though safety would be secured under ordinary circumstances it might not under slightly unusual conditions—as, for example, when a plate required a long time to develope and an extra quantity of ammonia. The stray light that would give a developable impression in a couple of minutes might develope into a highly-injurious stain after the lapse of a long and forced treatment with alkaline pyro. We have before us as we write a conspicuous example of this from the hands of a well-known professional photographer. He used a light which he considered perfectly safe; but on one occasion, having a very interesting negative which required tedious development, he from time to time held it before the light to examine its quality. When finished it was observed to be fogged in patches, and after a long examination it was discovered that the patches were caused by the light acting upon the plate through breaks in the backing of coloured collodion with which it was coated.

The plain conclusion to be derived from these experiments is that every photographer should test the suitability of the light he employs, or proposes to employ, by the touchstone of practice. Let him expose a plate under a mask (say) for four and for twenty minutes in the position it would occupy during development, and also for a briefer period in the favourite position for examining it for density or sharpness: the appearance it exhibits after development for (say) five and for ten minutes will be a sure guide as to whether or not he is working under a "safe" light.

OLD PRINTS.

Again the fading of silver prints has been prominently brought forward at the meetings of two of our photographic societies. At the last meeting of the Glasgow Photographic Association the cause of the fading of silver prints was the topic discussed, the subject being opened by Mr. Duthie, who expressed his opinions at some length, as will be found in our issue of last week. At the last meeting of the South London Photographic Society, our old friend and contributor, Mr. E. Dunmore, read an excellent paper entitled *Old Photographs* (a portion of which will be found on page 169), on which a highly-interesting as well as instructive discussion followed; as also did an adjourned discussion on whether prints made on ready-sensitised paper are more or less permanent than those on paper of home preparation.

At the latter meeting a large collection of old paper photographs, toned by different methods, were shown by the reader of the paper, the Chairman, Messrs. Foxlee, Ayres, York, and others, the date of the production of some of them being so far back as the year 1851. The oldest ones were a couple of small prints (evidently calotypes) shown by Mr. Ayres, which are still in a good state of preservation. So also were some salted paper prints, thirty years' old, believed to be toned by the old *sel d'or* process, exhibited by Mr. Foxlee. Others of a more recent date were in different states of preservation; the majority of them, however, it may be mentioned, although twenty years' old and upwards, were in a far better state of preservation than many we have seen which have not been produced as many months. In some of the examples (although they were said to have been mounted with gum, and had evidently been kept in a damp place, so that the mounts had become mouldy) the prints themselves were unchanged.

Although such an interesting collection of photographs of ancient date were shown, and an animated discussion upon them ensued, we regret that very little new light was thrown upon the subject of fading generally. However, one point—and an important one, too—appears to have been established, namely, that the larger the quantity of reduced silver is which forms the image the more permanent the picture is likely to prove. Also, that with strong negatives and strongly-sensitised paper a larger amount of silver is reduced, and, consequently, greater stability may be anticipated than when the conditions are reversed. This was tolerably well exemplified by one of the examples shown. It was an unmounted stereoscopic picture, taken some thirty years ago in a single-lens camera with two exposures. Owing to a difference in the exposures in the two halves they were of different density; hence one had apparently been shaded in the printing, for it was explained that from the first one side had been more vigorous than the other. The vigorous half is in a fair state of preservation, while the other has faded decidedly.

It will be remembered that, for a long time past, we have expressed a very decided opinion that prints which are made on strongly-sensitised paper from vigorous negatives are those which are always the most likely to prove permanent, and this notwithstanding that they may have had less care bestowed upon their production. Both before the meeting and since we have had the opportunity of closely examining in daylight a number of the specimens exhibited, as the yellowness is always more palpable in this than in artificial light.

Some of the sulphur-toned prints had not faded at all, in the literal interpretation of the term; for all the detail and vigour still existed, but the lights had become a sickly yellow. If this yellowness could be removed without otherwise altering the tone a rich, vigorous picture, full of detail and half-tone, would remain. This remark applies equally well to many of the prints which had been toned and fixed in the old gold and hypo. bath.

The fading of mounted photographs is frequently attributed to the mounting boards containing hyposulphite of soda. Mr. Dunmore appears to be of the opinion that the presence of this salt, pure and simple, in the print is not of necessity a source of fading. In his paper he describes an experiment he made to determine this point, which is worthy of note. He took a print that had been thoroughly washed and cut it in two. One half was then immersed in fresh hyposulphite solution and afterwards dried, the other half being kept for comparison. The half which contained the hyposulphite proved on keeping to be quite as permanent as the other, which was free from it. From this experiment, Mr. Dunmore is inclined to infer that much of the fading of mounted photographs is due to the presence of chlorine or some other deleterious material in the mounts rather than to hyposulphite of soda.

We may here mention a somewhat similar experiment we tried sometime since. A print was taken from the fixing bath and just drawn through a dish of water to remove the superfluous hypo., in order to prevent its crystallising out on drying. This brief washing, however, proved insufficient for the purpose; hence the crystals had to be rubbed off after the print was dry. We mention this circumstance merely to show that the print was thoroughly saturated with the salt. The print was then pinned up in a damp upper room. In warm and dry weather the print was dry and crisp, and in wet it absorbed moisture and became damp and limp. At the end of six months it showed no change whatever. In nine months (except that it had become very slightly yellow) there was no perceptible alteration. At the end of a year, however, there was a very marked change; for, not only had it become very yellow, but it had faded badly and only the darkest portions remained. One curious circumstance in connection with this experiment was that for nine months there was practically no change, but at the end of twelve months the picture had almost disappeared, showing that when once the fading set in it had proceeded very rapidly. This experiment, however, differs materially from that of Mr. Dunmore's, inasmuch as we took our print direct from the fixing bath and dried it, while he washed his thoroughly after fixing, and then submitted it to a perfectly-fresh solution of the hyposulphite.

During the discussion great stress was laid on the strength of bath upon which the paper was floated, particularly with regard to the "ready-sensitised" paper; and the opinion was expressed that the ready-sensitised paper of commerce is not so highly sensitised now as it used to be when it was first introduced, some fifteen years or so back. In connection with this subject Mr. York remarked that a great deal of the ready-sensitised paper now made is blotted off when it is removed from the silver bath; consequently it must necessarily contain less free nitrate than if it were allowed to dry spontaneously.

In the discussion on the strength of the silver bath as affecting the permanence of the prints one fact appears to have been overlooked, or it did not receive the attention it deserved, namely, that little or no real advantage is gained by increasing the strength of the silver solution unless at the same time the quantity of chloride in the paper be correspondingly increased.

A certain excess of nitrate of silver in the paper over and above that necessary to convert the whole of the chloride in the albumen into chloride of silver is required, but beyond that no material advantage is gained by a further addition. By increasing the quantity beyond a certain point we only get so much more free nitrate of silver in the paper which is washed out prior to toning; but, if the chloride in the albumen be augmented at the same time that the strength of the nitrate of silver bath is increased, a material advantage will be gained, as a greater body of chloride will be produced. It is this, and not the nitrate, which is necessary to form the image.

We learn that it has been decided to hold the next convention of the Photographers' Association of America at Cincinnati, the proceedings to commence in the Music Hall on July 29 next.

From a report of a meeting of the Chicago Photographic Association we find that the value of the combined green and orange light is being recognised in the western capital. Mr. Gentilé—an eminent photographer in that city—says that he has used this light in his dark room for some time and is much pleased with it. He has proved it to be all that has been claimed for it by writers in the English journals.

From a review of Dr. Liesegang's work on carbon printing in one of our American contemporaries, we find among those who are credited (whether by the author or the reviewer we cannot tell) with aiding in bringing carbon to its present state, the name of "Mungo Park." As the intrepid Abyssinia traveller is understood to have "shuffled off this mortal coil" long antecedent to the first inception of carbon printing we imagine that there must be some misunderstanding existing. Presumably, our lately deceased Scottish *savant*, Mr. M. Ponton, is meant. He, at anyrate, had some small claim to be mentioned in such connection, whereas Mr. M. Park is not known to have had any.

It is lamentable to find that any professional photographer can entertain such contracted ideas as to close his account with a respectable firm of dealers in photographic materials solely because they also supplied their goods to photographic amateurs. But it stands on record in several American photographic journals. The name of the photographic firm is given as L. M. Melander and Bro., Chicago. Has any reader ever heard of this firm before, especially in connection with advances of any kind whatever in photographic art or science? They write—"We have found the practice of amateurs to work positive injury to our business, and we are compelled to do what we can to discourage this amateur business in order that we may protect ourselves." The other Chicago professionals apparently reprobate such sentiments, as the foregoing enunciation only excited amusement.

One of the most singular facts in connection with explosions of the mixed gases at magic lantern exhibitions is the rarity with which a fatal accident is the direct consequence of the explosion, and the sad affair at Chadderton appears to offer another instance in the same direction. In this case, as our readers are aware, it was ether and oxygen that were being used; but Mr. Lewis Wright (an expert in all lantern matters), in a communication to a contemporary, states that the apparatus could not have been one made by the inventor of the "ethoxo." He writes:—"I cannot imagine an accident with proper apparatus properly used; but it is necessary to state that a great deal of ether apparatus is being offered to the public which contains elements of great danger." It is well to call attention to this statement of opinion, as it would be a great pity that a useful apparatus should unjustly be credited with a terrible accident.

No one could speak on such topics with greater weight than the gentleman to whom we refer. He has devoted much time to perfecting of plans for exhibiting on the screen all kinds of optical effects and arrangements. The class of phenomena exhibited at the London and Provincial Photographic Association at the end of last month is his especial study; indeed, many of the slides then shown were made by him. Those of our readers who do not possess his work on *Light*, published some little time ago, cannot do better than provide themselves with a copy. It is not very expensive, it explains many phenomena having the closest relation to photography, and enters into the fullest details of the best manner of projecting on the screen all phenomena of polarisation, interference, and other chromatic effects.

The present—the fifty-fourth—year of the British Association for the Advancement of Science witnesses a novel departure, the meeting, as our readers will remember, taking place at Montreal, on the 27th August. Naturally, all arrangements, election of officers, and soforth, have to be made earlier than usual on this occasion, and already a complete list of officials, headed by the President-elect, the Right Honourable Lord Rayleigh, D.C.L., F.R.S., Professor of Experimental Physics in the University of Cambridge, is published. Amongst them we notice few names connected with photography. It is expected that the gentlemen who will deliver public lectures, which form so popular a feature of the week's entertainment, will be Mr. W. Crookes, the Rev. Mr. Dallinger, and Professor Ball. One of the subjects selected by the committee for special discussion is the "Connection of Sunspots with Terrestrial Phenomena." Most liberal arrangements have been made by the railway and steamship companies; indeed, one company—the Canadian Pacific Railway—offers free travelling to all members of the Association from August 1st to the period when the excursion to the Rocky Mountains takes place, and for this it offers a free ticket to one hundred and fifty members.

We need not inform our readers that photographic work of the highest quality is done in Canada, and we do not doubt that all photographers joining the meeting will be welcomed by their *confreres* across the water. If they should be inclined to take cameras and plates they will be able to enrich their albums with views entirely different in character from such as they would be likely to obtain at home.

The addition of only one per cent. of ammonia to water lowers its freezing point about two degrees, while potash only reduces i slightly over one degree, and soda a little over a degree and a-half. t

---

We extract the following full details of M. E. L. Aude's mode of refining shellac. Three and a-quarter pounds of soda are dissolved in nine and a-half gallons of water contained in a small boiler or kettle. Eleven pou ds of crude shellac are added in small quantities at a time, giving a turbid solution possessing the characteristic odour of shellac and a violet-red colour. The liquid is boiled for a few minutes, and, while hot, a wooden air-tight cover is cemented on the vessel. When the liquid is quite cold the cover is removed, and the thin cake of fat which is found on the surface is separated. The solution is filtered through linen, the clear filtrate slowly decomposed with dilute sulphuric acid, and the resulting precipitate washed with water till no acid reaction remains. The washed resin is now pressed and melted in boiling water, when it can be shaped with the fingers. This shellac is cooled in water containing glycerol, and, when hard, is dried. The refined shellac forms yellowish-white, glistening tufts which, when dry, are yellowish-brown. It should entirely dissolve in alcohol.

The value of photography for educational purposes—using the word in its true sense—is well seen in a communication from Mr. C. T. Gatty, the Curator of the Mayer Museum, Liverpool (who is now travelling in Greece), to Sir James Picton, Chairman of the Committee. Mr. Gatty says:—"Although it is impossible by means of photography or drawings to give any complete idea of the beauty and grandeur of the position of these ancient buildings, it is not difficult by such means to give the student a very fair notion of their architectural features, their respective dates, their various purposes, and their sculptured decorations. I have, therefore, made a selection of photographs illustrating some of the more interesting matters suggested by the above-mentioned points." With such noble monuments around, telling him of the intellectual advancement and the artistic culture of those who erected them more than two thousand years ago, Mr. Gatty must have had an *embarras de richesse* to select from, but he would appear to have chosen well. He alludes to a connection, or resemblance, in style shown in the earlier Greek ornaments as instanced in those found at Mycenæ, with the Anglo-Saxon at one extreme and the Maoris at the other, and links them with Egyptian, Assyrian, and Phœnician results. One collection of photographs is to illustrate these points. He has a photograph of the Theatre of Dionysius and other views as interesting as they are instructive. Altogether, when collected in one spot, there can be no doubt that Mr. Gatty's small collection will draw many visitors and be of great value.

The celebrated Portuguese amateur, Carlos Relvas, has just appeared in a new *rôle*. In the last number of *La Nature* is described and figured a new lifeboat, of which he is the inventor, and which presents such novel and ingenious features that it has been the subject of a special Government trial, through which ordeal it has passed very satisfactorily.

The continually-increasing number of advertisements of photographic apparatus for amateurs is a most striking feature of the progress photography is making. There must be thousands of amateur photographers throughout this country alone, and in America the desire to photograph seems to have become almost a craze. The *New York Times* has a very droll article on *The Real Cause* (that is, of great increase of insanity)—which it gravely proposes to set down to the rage for amateur photography, and the state of mental vacuity caused by the never-ceasing variety of dry plates and the formulæ for developing them. The article concludes by saying that—"It is estimated that the different combinations of chemicals which may be used as 'developers' amount to 37,218, and the unhappy man who begins the search for the very best 'developer' is on the high road to insanity. What is said of plates and 'developers' applies also to 'fixing baths,' 'toning baths,' and the countless processes which various photographers have adopted. Each photographer has his own pet processes, and looks with scorn on all others. If the beginner knows only three photographers these are quite enough to overthrow his mental balance. No matter on what question bearing on photography he may consult the three photographers, each one will give him an answer totally different from those of the other two. There are few men strong enough to preserve their serenity in this conflict of opinion. The intellect of the ordinary amateur reels under it, and he becomes a hopeless mental wreck. Our lunatic asylums are now crowded with men who rave of developers and toning baths, and who solemnly conjure a visitor by all he may hold sacred never to use Smith's or Robinson's plates, but to stake his eternal soul on the supreme excellence of Thompson's plates and Jackson's 'developer.' Every amateur who has tried dry-plate photography and preserved his reason will have no difficulty in attributing the recent growth of insanity to the introduction of dry plates. We need search no further to find out why our lunatic asylums are crowded. The insidious dry plate and the plausible developer furnish the explanation that medical men have sought in vain."

MR. W. B. WOODBURY.

Few names, probably, are more familiar to photographers throughout the world than that of the subject of our illustration. Not only has Mr. Woodbury's name been permanently identified with an important printing method of which he was the inventor, but in many other departments of photography he has been well known for many years past as an ardent and indefatigable worker. To give anything like a complete list of his achievements as an inventor would require more space than we could afford in a single number, but the processes by which his name will be specially handed down to posterity are the Woodburytype, photo-filigrane, and the Stannotype, all three involving the same principle but with different applications. Not only as an inventor is Mr. Woodbury known, for he is also a skilful practical photographer, and no one who has had the privilege of inspecting his Italian series of landscapes will be inclined to deny him the right to the title of artist as well as photographer.

The number of medals and other awards that Mr. Woodbury has gained is very large. A portion only of them fills a goodly-sized frame, forming a trophy of which any one might be proud. Curiously enough, until comparatively recently, England was almost the only civilised country that had failed to recognise the merits of her own son; but this defect has been remedied by the award of the progress medal of the Photographic Society, and, again, a medal for the Stannotype process at the last exhibition.

A VESSEL FOR LIQUEFYING EMULSION AND COATING PLATES.

Various devices and means for retaining gelatine in a fluid condition while being employed in the coating of plates have been brought under public notice. That which we are now about to describe will, we venture to affirm, approve itself to most readers as fulfilling in every essential feature the requirements of an effective pouring vessel for this purpose. It was exhibited by Mr. A. L. Henderson at a recent meeting of the London and Provincial Photographic Association, where it was received with much favour.

A porcelain vessel—of a shape suggestive of a rather narrow marmalade jar, but having a suitable lip for pouring from and with a species of flange round the upper edge—is made to fit into a tin jug having a handle. This jug is so much deeper than the interior porcelain vessel as to permit of a space of a few inches between the two at the bottom; that is to say, the bottom of the porcelain vessel when *in situ* is a few inches above that of the metallic jug. In this space is fitted on gimbals a tiny lamp of the night-light *genus*, which always preserves its level position like the card of a mariner's compass, no matter to what extent the vessel in which it is contained may be tilted; even if laid on its side or turned bottom up the lamp will not be affected in the slightest degree. The heat from this little lamp is sufficient to ensure the gelatine being retained in a fluid form during the period it remains lighted. In so far, therefore, as its functions of heating are concerned the appliance is a success.

But the lamp has a still further use. In front of the tin vessel is a square aperture glazed with non-actinic glass; and the lamp, in addition to giving sufficient heat to keep the gelatine in a fluid state, through this pane also gives light enough to permit of the operation of coating the plate being conducted with perfect safety.

Inside of the porcelain pouring vessel is a tubular funnel reaching from top to bottom, over the lower end of which is tied a piece of filtering material. Into this funnel is thrown from time to time lumps of unmelted emulsion which, from contact with that still remaining in the vessel, soon become liquefied, and the emulsion filters out into the larger vessel by which it is surrounded.

The apparatus thus briefly described has much to recommend it. It is easily and cheaply constructed, and is said to perform its work well.

A FRENCH *LITTÉRATEUR* ON MR. CECIL V. SHADBOLT'S BALLOON PICTURES.

In the current number of *La Nature* is an interesting and appreciative article, founded on the now well-known examples o balloon photography executed by our esteemed correspondent, Mr. Cecil V. Shadbolt; and, knowing the interest taken in the subject by so many of our readers, we here present it in full:—

Is it necessary (asks M. Tissandier, the editor) to dwell upon the interest attaching to this problem of balloon photography, which has already attracted the attention of aëronauts, photographers, and military engineers? To collect plans high up in the air, to impress upon the negative the images of clouds and the beautiful optical effects one admires in higher regions of the atmosphere, or in time of war to bring down to the earth photographs of a fortress or of the enemy's camp—how marvellous!

M. Nadar long since made many essays to take photographs from a balloon, and obtained encouraging results in the car of the captive balloon moored in the Hippodrome, in 1868. The photographic apparatus was suspended at the extreme limit of the cable, two hundred metres high. The view taken showed the Arc de Triomphe and the streets leading to it; but the picture leaves much to be desired in the matter of sharpness. M. Dagron succeeded in taking a panorama of Paris from the car of the captive balloon of 1878 at a height of five hundred metres. In 1880 M. Paul Desmarets, at present Director of the Meteorological Observatory at Douai, greatly advanced this question, and our aërial colleague published in *La Nature* an interesting article upon the experiments, with an engraved reproduction of the pictures he obtained—one representing the earth from a height of eleven hundred metres, and the other the clouds and sky at thirteen hundred metres. The originals of these curious engravings are now at the Museum of Arts and Manufactures.

At a more recent period fresh experiments were undertaken in America, and Colonel Laussedat was lately good enough to send me a photographic view of the city of Boston taken from a balloon, with regard to which he stated Mr. Glaisher, the learned English meteorologist, had written to him. The proof is certainly very curious, but, like the others, fails in the point of sharpness, and, further, appears to have been taken at a low elevation.

During the last exhibition of the Photographic Society of London, the attention of visitors was drawn to a magnificent photograph taken from a balloon at the height of about six hundred and fifty metres, by a clever English operator, Mr. Cecil V. Shadbolt. This photograph is, beyond doubt, the most remarkable obtained up to the present time from the car of a balloon. Its author has, at our request, kindly sent us a copy, which we reproduce below with the utmost exactitude of which wood engraving is capable.

The negative was obtained by the gelatino-bromide process with an apparatus fixed by a kind of movable hinge to the ledge of the car of the balloon "Sunbeam." This balloon has already been used for five photographic ascents by Mr. Shadbolt and his assistant, Mr. William Dale.

We have received five aërial photographs from the clever worker. The first was executed at a height of eight hundred and fifty metres, the second at about five hundred, the third at nine hundred and twenty-three, and the fourth close upon a thousand metres high. The photographs resemble maps of great delicacy, in which may be recognised houses, roads, fields, and the Thames; but certain difficulties still remain to be faced.

The fifth proof—the one we reproduce—on the contrary, borders upon perfection, and must be described as a great step in advance. It was taken at a height of six hundred and fifty metres near Stamford Hill, in the North of London. The railway represented shows the junction of the Enfield line upon the Great Eastern with that of Tottenham and Hampstead. A railway bridge crossing the road is seen, the shadow of the bridge being clearly visible and giving remarkable relief to the picture. The railway station is seen and a train in motion with the smoke of the engine. A house appears beautifully sharp in the print; we can plainly see with the aid of a lens its chimneys, back yard, &c., while we are also enabled to recognise passers-by arrested in the act of locomotion. Finally, the tramway. The other parts of the photograph represent roofs of houses in regular rows, side by side, with similar gardens all of the same size, after the English fashion. To the left may be seen trees clearly delineated. We again add that we allude to the *photograph* itself, and that our engraving can only give an imitation by no means closely approaching the original.

We congratulate Mr. Cecil V. Shadbolt upon the beautiful results he has obtained, which, we trust, will soon lead to still further advances.

STANNOTYPE.

No. VI.

The photometer scale described in the last article may be used in two different ways. If upon glass, the various tints may be marked with opaque ink, with figures representing their different values, so that, as in the Warnerke scale, the last—or, in this case, the desired—reading will be given by the representative figure in white upon a slightly-tinted ground. But this system necessitates constant reference to the photometer, which must necessarily par-

W. B. WOODBURY.

INK-PHOTO, SPRAGUE & Co LONDON.

take of the character of an ordinary printing-frame, each examination requiring the opening of the hinged back. It has this advantage, however—that a number of frames may be watched at once by its means.

Thus, supposing that we have a number of reliefs to make at one time, and that we know the printing value of the different transparencies and the number on the photometer scale that best suits each individually, we have only to put them out along with the photometer, and as each tint is registered the corresponding frames are taken in, and so on until all are finished.

But this is a somewhat troublesome method upon which to work. The system involved in the Woodbury photometer is far preferable—that is, the colouration of the sensitive paper to a tint or scale of tints visible without any interference with the apparatus. The graduated scale, described in the last article, is perfectly applicable to this purpose. If printed by the stannotype process upon paper in the ordinary manner, with ink of a suitable colour to represent the changes that occur in silvered paper under the action of light, we have all that we require. If a small aperture be cut or punched out of each "tint," so that a portion of the sensitive paper is fully exposed to light, we have only to watch the moment when the colouration reaches the same depth as the surrounding tint bearing the number which we know to correspond with the transparency or negative we are using. The cheapness and the ease of preparation of such scales will recommend them to all who work either the stannotype or carbon process.

It was mentioned in the last article that each printing-frame might have its own photometer; but, preferably, we should say that each transparency or negative should have that distinction. The printing-frame may be used for *clichés* of all types and all densities, and will thus require a range of tints to suit all. But in the case of a transparency or negative, with its own photometer attached and its printing value or requirements known, a single tint of known value or, at most, two or three are all that are requisite.

Here we may accept a suggestion of M. Leon Vidal to provide each *cliché* with its own photometer of three tints only, the centre one of which represents the exposure necessary; and when the sensitive paper is coloured to that tint the two outer ones will be respectively lighter and darker, and, in fact, form a sort of marginal reference. Such scales in paper can be readily made either by the stannotype or carbon processes. A very handy form of photometer scale of this kind was described by Mr. W. E. Debenham, we believe, in our ALMANAC a few years ago. It consists of a scale of tints, printed in carbon tissue, with an aperture in each to permit of the exposure of the slip of sensitive paper; and we can answer that it has served remarkably well for a variety of purposes in connection with carbon printing.

But, for the longer exposures necessary to the production of printing reliefs, it is scarcely possible to arrange either a sufficiently-elastic scale of tints or a sufficiently-slow printing paper to suit the purpose; it is, therefore, necessary to resort to special means—such as those adopted in the Woodbury photometer—for attaining the same result, namely, the interposition between the sensitive paper and the light of a coloured medium in the shape of a piece of yellow or orange glass, or, preferably, a thin sheet of coloured gelatine, several of which of varying depths of colour may be kept at hand. For ordinary carbon printing the range of tints will be found quite sufficient when used in this manner; but if placed upon glass and employed after the manner of the Warnerke screen, any depth of colour may be obtained and utilised by merely changing the character of the ink.

So much having been said of the photometer and its use, we have little more to add in connection with the printing operations, unless it be to point to the desirability—if not absolute necessity—for the employment of a backing of sheet india-rubber behind the tissue. The presence of so large a proportion of hygroscopic matter, in the shape of glycerine and sugar, renders the tissue particularly prone to absorb moisture during a long exposure; and, as the conditions which favour such absorption are generally more prevalent on a dull day when long exposures are more particularly necessary, the value of this suggestion will be appreciated. If it be neglected various defects may ensue, which will be dealt with under the head of failures. We shall next week proceed to describe the development of the relief.

THE EFFECT OF SHEARING STRESS ON A SENSITIVE SALT.

AT the last meeting of the last session of the Photographic Society I gave a paper on the above subject, which, at the time, was commented upon both in the *Photographic News* and in THE BRITISH JOURNAL OF PHOTOGRAPHY. In the latter journal the effect was laid to an abrasion of the film, and not to stress on the particles of silver bromide. Since that time I have carried on a few experiments on the subject, the results of which seem to point to a different conclusion.

When writing-paper was placed between the film and the writing point, though an image of the markings developed with apparently no abrasion, yet it might be due to two causes—one to organic matter from the paper pressed into the film, or to the fact that an abrasion might have taken place imperceptible to the eye. In order to test what effect abrasion really had, a gelatine plate was marked with a point, and a small amount of abrasion could be seen. It was then placed in water and soaked for a few minutes, after which it was placed near a hot-water bath till the surface of the gelatine had melted, and no trace of any rupture in the gelatine could be traced. It was next allowed to set and dry and then developed. The phenomena I have described in my last paper presented themselves as before; but a remarkable thing occurred, viz., that the developed writing was as sharp as if the surface had remained unaltered by melting. This pointed to the fact that the real effect was produced *below* the abrasion.

To test this a plate was written on as before, the gelatine melted to the very surface of the plate, and a gentle rocking given to it to displace the sensitive salt next the glass. The gelatine was allowed to set again, and then developed. In this experiment the writing was *thickened* and *distorted*, showing that the seat of the phenomenon had been reached. I may remark that in the first-described experiments the plate was also rocked when the surface gelatine had melted, and this gave me an idea in what direction further search ought to be made. The destruction of the writing took place, as in my before-described experiments, by the application of bichromate of potash to the plate.

We have here, then, a further step in tracking this curious phenomenon to its source, and is in support of shearing stress exercised on the sensitive salt of the film, as against mere abrasion, since the altered sensitive salt was below the abrasion. W. DE W. ABNEY, F.R.S.
—*Photo. Journal.*

HALATION.

[A communication to the Dundee and East of Scotland Photographic Association.]

NOT being able to see in what way Mr. Geddes could reduce halation by placing a blackened card behind the sensitive plate during exposure, I, nevertheless, thought it only right to make a trial of the plan before coming to a conclusion on the matter. One little experiment led to another, and I will briefly state the results at which I arrived.

I have here a simple, non-achromatic lens of bi-convex form. If you catch the reflection of a bright object (such as a jet of gas) upon it you will find that there are two images to be seen—first, an erect image from the front surface of the lens; and, second, an *inverted* image from the back surface of the lens. A piece of ordinary glass would have done just as well, but the curves of the lens giving an erect image from the front and an inverted image from the back allows the back image to be at once recognised.

One quarter of the back surface I have covered with carbon tissue *in optical contact with it*; another quarter I have covered with a backing of starch and "deep orange chrome;" the rest of the back surface is uncovered.

Now, you will find, if you stand so as to catch the *inverted* image upon the uncovered part, that this back reflection is almost as powerful as the erect image thrown by the front surface. Turn the lens in your hand so as to bring the *inverted* image upon the orange backing, and you will now find the back reflection is only half as powerful as it was. Turn the lens further and bring the *inverted* image upon the carbon tissue, and you will find that it has all but vanished. Once more bring the inverted image upon the uncovered part of the back surface, and while there place behind and in contact with the glass a blackened card. You will find that this has not the slightest effect upon the back reflection.

From this demonstration I conclude that carbon tissue is a better backing than the orange chrome, and that the blackened card has no effect in reducing back reflection. Actual experiment with the camera confirmed these conclusions, the orange chrome giving slightly better results than might have been expected, but in no way equal to the backing of carbon tissue.

That halation is not entirely cured by backing the plate, even with carbon tissue, may be due either to the fact that the back reflection is not entirely obliterated by the backing, or that other causes are to be found for what is not explained by this cause.

If you examine the inverted image reflected from the surface of the lens *backed by tissue* you will find that it is very faint; and, since in actual practice the light is still further reduced by first having to penetrate the film, it is reasonable to suppose that any little light reflected from such a backing must be very weak indeed.

From these and one or two other experiments I conclude there are other causes at work; and, stating what appear to me to be the chief causes of halation in order of importance, I would place:—First, reflection from the back of the plate (not entirely obliterated by any backing). Second, reflection from the illuminated particles of bromide of silver acting upon adjacent particles. Third, reflection from particles of dust floating in the camera in the vicinity of the plate, as can be proved by filling the camera with dust and exposing a properly-backed plate. Fourth, a certain *chemical* condition of the plate—halation being often very pronounced where the physical conditions seemed to be entirely against its production. J. K. TULLOCH, M.D.

EXPERIMENTS WITH A PYRO.-SULPHUROUS DEVELOPER.

"NECESSITY" is, according to the old proverb, "the mother of invention," and out here in Lucerne, after buying much experience as to the difficulties and delays in getting parcels from London, my stock of sulphite of soda ran out all but a few crystals, placing me in a difficulty, as I did not care to adopt any other than this clean working developer. However, it had often occurred to me that sulphurous acid was the active principle of the developer so far as its clean working was concerned, a trace of that acid being used with iron developers in some transparency-making processes, and in bringing out the image by development on Hutinet's paper, extra brilliancy being the result of its employment.

The few crystals of sulphite of soda left out of my stock contained, of course, plenty of sulphurous acid, which ought to go much farther in its free than in its combined state. This sulphurous acid is easily liberated from the crystals by adding sulphuric acid to a solution of them. The latter acid unites with the soda; the evil-smelling sulphurous acid gas is set free, and for the most part is held in solution in the liquid. On previous occasions I had put a trace of sulphuric acid in my sulphite of soda developer to set free a little sulphurous acid, and it was found that the sulphuric acid must be added with moderation; so that some undecomposed sulphite of soda is always present, otherwise the surplus sulphate of soda produced by the decomposition gives to negatives the well-known yellow stain produced also by the carbonate of soda developer, and cleanliness is lost.

A solution was accordingly made consisting of—

SOLUTION A.

Water	1 ounce.
Sulphite of soda	20 grains.
Sulphuric acid	6 minims.

The presence of free sulphurous acid became evident from the smell. The proportion of sulphite of soda to the ounce generally in use for developing is rather under 200 grains, making a saturated solution the quantity of the salt in which varies with the temperature of the air. Consequently in the experiment now under notice an attempt was made to cause twenty grains of sulphite of soda to do the work usually allotted to about 200 grains.

To some of Edwards's developing (D) solution, which chanced to be at hand, consisting of pyrogallol, water, glycerine, and alcohol, I added enough bromide of potassium solution to act as a restrainer, and then thirty minims of the above solution (A), making two ounces of developer in all. The exposed plate was subjected to the action of this solution for a minute, and brushed while under it to clear away possible air-bubbles; then a little ammonia was added in the measuring glass to the same pyro.-sulphurous solution, which was poured back upon the plate. The result was a clean transparency, as if the developer had contained sulphite of soda in the ordinary way. The edges of the plate which had been protected from light by the frame were like bare glass after the development.

Over landscapes there is usually no trouble from want of light, and, whether it may be wrong or not in theory, I find it saves trouble, in mixing, to add the bromide of potassium to the stock pyrogallol solution once for all, and to add it rather liberally, for the power of bromide as a restainer is very much weaker than that of ammonia as an accelerator. The ammonia must be added very cautiously in the earlier stages of development, or mischief is easily done. It is not quite so easy to do mischief with erroneous proportions of bromide, of which it is better to have too much than too little. Of ammonia it is better to have too little than to much.

A developing solution was next made as follows:—

DEVELOPING SOLUTION B.

Solution A.	1 ounce.
Bromide of potassium	15 grains.
Pyrogallol	50 ,,

In developing thirty minims of this were added to two ounces of water, and used in the manner already described, care being taken not to overcharge with ammonia in the developing operations. The results proved that the object had been attained, and that the class of negatives usually obtained by means of sulphite of soda can be produced with one-tenth the quantity of that salt ordinarily employed, if the above pyro.-sulphurous developer, as it may be christened, be substituted.

There was more tendency with this developer to throw down an apparent deposit after the addition of the ammonia than is the case with the ordinary sulphite developer; this had no practically injurious effects, but nevertheless presented a problem, as it does with many other pyro. developers, for examination. In broad daylight two ounces of the diluted-for-use developer were made in the ordinary way, and the usual quantity of ammonia added. The mixture was made in a flat-bottomed glass tumbler, standing on a sheet of white paper on the ledge of an open window. The best method of observation was to look down upon the liquid, rather than to examine it through the sides of the glass. A series of very beautiful phenomena was then presented. At once it became evident that the dark deposit was not a solid one, but consisted of portions of the liquid darkened by the action of the air, after absorbing the oxygen of which they sank in the surrounding solution. A dark little star usually first forms near the centre of the surface of the solution, and sends down a dark shaft to the bottom of the liquid, forming a kind of stem, from which branches next spread along the top of the liquid, every now and then sending down a new shaft, as in the growth of the banyan tree. Gradually a most beautiful design is thus traced in liquid veins—a design more to be contemplated with satisfaction when produced in a glass tumbler than when produced over a plate in course of development.

On the supposition that the well-known freedom of the old sulphite of soda developer from this common class of irregular decomposition might be due to its viscosity, because of the large proportion of the salt it contains, I next thickened my ounce of pyro.-sulphurous developer by adding sixty grains of lump sugar to it. The experiment with the glass tumbler was repeated, and it was found that the irregular decomposition took place, but more slightly than before. Sixty grains more sugar were then added, with still greater retardation of the irregular decomposition, which always begins at points where the liquid is in contact with the air. By thus increasing the viscosity of the liquid its developing powers were made to closely resemble those of sulphite of soda, the proportion of which, with the sulphuric acid, can no doubt be reduced with safety; for it is not likely that the most economical proportions have been discovered in a first experiment.

The stock solution of developer B is of a golden yellow colour, just the colour of a weak solution of chloride of gold. Herr Brunck, of Lucerne, tried a few experiments with it, to see if the colour were due to free bromine. He found that chloroform would not dissolve the colouring matter, and after some further research we came to the conclusion that no free bromide is present, and that the tint is wholly due to some feeble discolouration of the pyrogallol.

After two drachms of sugar had been added to the stock developer it became evident, in the tumbler experiments, that the diluted developer was more subject to air-bubbles, so as to render brushing the plate under the unaccelerated developer all the more necessary. With but sixty grains of sugar this objection was not so apparent. Therefore, if sugar be used at all, it is best to keep the preparation low enough to just produce the desired effect and no more. When a viscous developer is used, and the normal amount of rocking of the plate is given, the surface decomposition has its irregular nature as to locality more masked, but it is probably always present in all pyrogallol developers, more or less.

When it came to actual developing I could see little or no advantage from the addition of sugar, so I scarcely recommend its use for practical purposes. The streams of partially-decomposed liquid in various pyrogallic developers seem to do no harm; the darkened liquid is not more active than the rest on the plate, but more inert, having already absorbed oxygen. It may be asked why sulphurous acid is not used at once, instead of producing it in the developer by the decomposition of sulphite of soda. This has not been tried by me, since a bottle of solution of sulphurous acid would be an unpleasant thing to carry in baggage, especially should any breakage occur; this objection does not apply so strongly to its use in immovable photographic establishments. I have not seen that excess of sulphurous acid has a perceptible effect in slowing the plate, although sometimes enough of it has been liberated by sulphuric acid, in my experiments, to produce a developer covered with smoke after the addition of the ammonia, because of the dry decomposition set up in the air, between free ammoniacal gas and sulphurous acid gas.

A gelatine plate directly after development is practically a swelled sponge, with its pores full of decomposing developer, the surface only of which can be quickly washed. Fortunately the dark product is very soluble in water, and by successive washings of the film in clean water can for the most part be removed in ten minutes. This is the part of the operations where thorough work gives the cleanest negatives. If the fixing or the clearing solutions acquire more than a trifling tint of yellow the washing after development has not been well done, the colour of the two solutions just mentioned being a safe index.

Will you allow me to suggest that writers for the photographic press who recommend the use of alum shall henceforth always print which of the many alums they mean. "The common alum of the shops" is meant, say some; but Mr. A. Spiller has published that common alum is usually potash alum, while two large London chemists told me that common alum is ammonia alum. Then, again, what are the merits and demerits of chrome alum—which, by-the-bye, is called alum because it contains no alumina? Alumina inadvertently precipitated in a gelatine film is so insoluble that there is no getting it out again, so possibly chrome alum may be greatly superior, if any accidental deposit from it can be dissolved out by reagents. Added to this, its powers of hardening the film are much greater than those of common alum—whatever that may be—so that weaker solutions of chrome alum can be used. In future our literature would be more exact and scientific if those who recommend the use of alum would say whether they mean potash alum, ammonia alum, cæsium alum, chrome alum, iron alum, Roman alum, rubidium alum, soda alum, or thallium alum, instead of allowing the reader to try to guess which alum they mean.

Without some experiments of a strictly scientific and comparative nature it is difficult to be certain whether by the sulphite of soda developer details are lost in the highest lights and deepest shadows, as Mr. B. J. Edwards believes. At first I thought this was so, especially when I photographed a castle, and discovered its magnificent backgrounds of the Rigi to be absent on the developed plate. But that plate was exposed in a bright light at midday, under which conditions mountains blue and white in the distance are as difficult to catch as clouds, when the foreground has to be good. With better conditions of lighting I obtained the view all right, and with the sulphite developer. If some of the few well-known photographers alluded to by Mr. Edwards will come forward with their names and say that after a few months' constant use they abandoned the sulphite of soda developer, and why they did so, such practical testimony must carry great weight. If a stained negative give a double chance of printing well, that might as well be brought about by staining a sulphite negative as by bleaching a discoloured one. W. H. HARRISON.

Lucerne, Switzerland, Feb. 16, 1884.

OLD PHOTOGRAPHS.

[A communication to the South London Photographic Society.]

THE title of my paper having been chosen I am in a measure compelled to suit the subject to it. "Old photographs!" There is a ring about the words "old photographs," sentimental as well as scientific—perhaps more so. I question much if there are any other old existences, save and except old letters, that have the power to flood the memory with pictures of the past in the same degree as will "old photographs." Generally "old photographs" convey pleasant expressions, and are reminiscences of bygone hours of excitement, enthusiasm, and expectation. They remind one of glorious rambles, genial companionships, and pleasant friendships—the golden and happy side of a lifetime.

I now particularly allude to landscape work, than which no occupation could be devised more conducive to health and pleasure—combining as it does active bodily exercise with a reasonable amount of mental occupation. With portrait photographs it is somewhat different. The actors may have passed away, leaving but old memories behind, fused in the crucible of time which by the magic of an "old photograph" separates. The originals once again stand before us vivid and distinct, as though it were but yesterday the portraits were made. One memory awakens another. Incident upon incident crowd the imagination, spirits of the past rise at its bidding, and that one—maybe a poor, weak, inartistic presentment—exerts an influence (painful or pleasant as the case may be, but all softened by the alchemy of time, the glow of pleasure veiled, the sting of pain removed) which, in all probability, is possessed by no other existing entity.

The occupation of looking through a collection of old works and comparing them with recent ones is far from labour thrown away, especially if they have been one's own work. We may recal an experiment the results of which were thought little of at the time it was made, but which now, a new light being thrown on it by experience, becomes a valuable hint. The extreme importance of making notes of our experiments, if carefully performed, can scarcely be overrated. Memory is apt to play us tricks if not supported by written notes, especially if a good number of similar experiments are made—generally the case in working up a new process. A very little variation may mean success or failure, and it is just as well to be on the safe side by reference to methodically-kept memoranda. Since photographs we call "old" were made photography itself has assumed a new garb and an importance in the arts and sciences that could hardly have been anticipated. Therefore, early experiments, viewed by the light of modern knowledge, may be of considerable use in assisting the solution of some present difficulty.

PIONEER SERVICES RECOGNISED.

The thanks of photographers of the present day must be accorded to those persevering pioneers and experimentalists who, when the art was in its babyhood, so nearly bit on the ways and means we now adopt, and which, even after a lapse of over thirty years, still form the foundations of our process. In a measure we seem to be reverting to the original plans. Paper was most successfully used in the old calotype process—one of the earliest processes discontinued—to give place to its diaphanous and brittle successor—glass. Now, again, paper is being used extensively for sky negatives and also as a support for gelatino-bromide films for landscape work on roller slides, and also in compressed blocks. Pyro. development has again come to the front in place of iron, with this difference—alkali is added instead of acid. All through the processes of negative-making changes continue to be rung on similar materials, and no absolutely new departure made. With mechanical processes wonderful improvement has been effected. The working of them is, however, in comparatively few hands. I believe Swan produced carbon prints commercially as far back as fifteen years—perhaps earlier; but it is comparatively of late that carbon and mechanically-produced prints have become so much used, especially for book illustrations. Chemical processes of production are, and in all probability will, continue to be the kind with which the majority of photographers will occupy themselves.

The very fact of continuing the work so much on old lines suggests the question—In what manner and degree is a modern superior to an "old photograph?" The answer is somewhat difficult to give. Is it in permanency? Surely not; for here we have prints that have proved their claim to be called "permanent" by the fact of some twenty, thirty, or more years of existence, and are still bright, good, and apparently unchanged. Is it in delicacy or quality? No; we may fairly say some photographs were produced of as good quality in the early days as at the present time, judging from the examples we have the opportunity of examining. Then what is the improvement obtained by thirty years' experience if it be not in permanence, delicacy, or quality? No other conclusion can be drawn but that the superiority, where any exists, is entirely outside the chemical qualities or the actual making of the photographic print, instead of which it rests altogether in the artistic treatment and feeling imparted to the subjects, aided by skill naturally acquired through familiarity and practice.

MANIPULATION AND ARTISTIC SKILL.

I said "some" photographs were equal in quality to those now produced. It must be borne in mind that thousands and tens of thousands of photographs are made now to one made formerly. Manipulative skill is possessed by thousands where one was skilled in the early days, and the consequence is excellent photographs are exhibited wherever we turn—from the London shop windows to the country cottage. We can scarcely go anywhere where good photographs are not. In the early days it was a rare thing to see a thoroughly good photograph—not because they could not be produced, but by reason of their limited number and there being so few to produce them. Beginners or unskilled persons generally turned out that kind of effect called "soot and whitewash." This, with the very imperfect fixing and washing, owing to the but partially understood reason why it should be different, soon translated the "soot-and-whitewash" effect into a colour wash and fade, and upon the evidence of such imperfect productions the public have concluded that the photography of the present day has become a wonderfully-improved *process*.

The improvement, as I have already suggested, is in the artistic treatment rather than anything else, and this I believe to be the line upon which improvement will run in the future. Gradually photographers will perceive the inartistic faults in their otherwise perfect work to which they are now blind; for it is naturally a somewhat difficult thing for a man to see faults in his own photographs—perfect in a manipulative sense, but seriously or slightly defective in composition or the arrangement of light and shade. As a fact, to him the faults do not exist. He, therefore, cannot be expected to see them; and it is only by art-education, no matter how acquired, that he will at length cast off this manipulative blindness, so to say, and make his works as well as judge of them by the higher standard.

There is no doubt that the extra sensitiveness of our films will do much to alter the character of future work. This, with the unquestionable advantage of having plates ready for use at a moment's notice, instead of waiting for the completion of the many preparations necessary to be made in the old wet-plate days, must exercise considerable and favourable influence in securing negatives. EDWARD DUNMORE.

(To be concluded in our next.)

LECTURES AT THE ROYAL INSTITUTION.

PHOTOGRAPHIC ACTION.

THE second lecture of the series was given on Saturday, the 8th inst., to the same audience as attended last time. Captain Abney commenced by showing the two molecular states of gold—the one being larger than the other, as shown in the prints developed with chloride of gold on uranium and iron salts respectively. On the former the gold had a decidedly ruddy tinge, whilst on the latter green. A reference was next made to the action of light on organic bodies—such as the tanning action of sunlight on the skin—and also on the fading of dyes, which he showed to be due to their absorption of oxygen.

This part of the subject was also illustrated by the action that light had had on a deal board on which had been laid a paper of printed matter, and which had been exposed to the sun for some time. The juices contained in the wood had been darkened by the light penetrating through the paper, the parts beneath the printed matter alone remaining undarkened. A reference was also made to the change effected in glass by the continued action of light. The lecturer next touched upon the number of molecules existing in chloride of silver of an inch in area and the one-thousandth part of an inch thick, which, for purposes of a rough calculation, he assumed would be blackened in one minute in the bright sunshine. He stated the number to be 1,728 with twenty-four 0's placed after it. A calculation was next made as to the energy of sunlight in separating the atoms of chlorine from silver chloride. This was founded on the fact that the heat resulting from the melting of nine cubic inches of ice was equivalent to the production of one-horse power. Herschel, it was stated, had found that sunlight would melt $\frac{7}{1000}$ of an inch of ice per minute, which was equivalent to being able to raise 255 pounds one foot high.

Supposing $\frac{1}{1000}$ part of this energy of radiation was absorbed by the chloride, that was equivalent to raising one-quarter of a pound one foot high. The weight of the chloride of silver of $\frac{1}{1000}$ of an inch thickness and one inch area was stated to be about four grains, of which one grain was chlorine. As only one half of this was released the energy expended was equal to raising the liberated chlorine 2,900 feet against gravity, so that had only gravity acted each atom of liberated chlorine could have been raised that distance, but as the molecules were only some $\frac{1}{12000000}$ to $\frac{1}{2500000000}$ of an inch apart it followed that the chlorine must have been held to the molecule of silver with a much greater force than that of gravity.

The next subject touched upon was the action on silver chloride and silver salt by short exposure. The developing action he attributed to the energy of molecular attraction acting on the slowly-depositing silver. This he enforced by showing the magnetic curves produced by the action of a magnet on iron filings; by a silver tree twenty-five years' old, which had been started by Faraday, at Woolwich, who was lecturer on chemisty at the Royal Military Academy. The spicules of this tree were three inches long in some cases, and beautifully showed the molecular attraction, which was effective only when slow deposition of silver took place. A third experiment in proving this was shown by the molecular deposition of lead under the influence of an electric current in a solution of acetate of lead. The formation of crystals was well shown, and was stated to be similar to that which existed in building up the photographic image. A calotype print was partially developed to explain the method of development. A wet plate was exposed in the camera, and it was endeavoured to develope it in the light of the lantern, but the yellow glass used was evidently of such a non-actinic kind that instead of an image the plate fogged. The matter, however, was subsequently remedied by developing a negative in a dish.

The effect of viscous bodies, such as glycerine and acids, in retarding the reduction of silver nitrate was next alluded to, and pointed out to be a necessity for proper development.

The alkaline development and ferrous citro oxalate developers were also touched upon; the slow reduction of silver chloride and silver bromide being shown when a physical restrainer, such as gelatine, or a chemical restrainer, such as bromide of potassium, was used.

RECENT PATENTS.

PATENT APPLIED FOR.

No. 4,404.—"Method or Process of Colouring Photographs, Drawings, Printed Subjects, or the like." B. P. Stockman, C.E., 3, Poet's-corner, Westminster, Middlesex.—*Dated March 5, 1884.*

PATENT SEALED, March 7, 1884.

No. 4,471.—"Improvements in Means for and Method of Producing Designs upon Paper or other Fibrous or Soft Material." R. Brown, R. W. Barnes, and Joseph Bell, Liverpool.—*Dated September 19, 1883.*

NOTICE TO PROCEED.

No. 5,204.—"Improved Method of Producing Surfaces for Mechanical or Ink Printing by Means of Photography." Harrison Garside, Manchester.—*Dated November 2, 1883.*

SPECIFICATION PUBLISHED DURING THE PAST WEEK.

FRAMES FOR PHOTOGRAPHS AND OTHER PICTURES.

This invention, which received provisional protection only, is by John Frederic Cooke, of 6, Oxford-court, Cannon-street, London. The specification is as follows:—

It is especially adapted to cases where the photograph or picture is seen through a piece of plate or other glass having a bevelled edge, and nothing outside such bevelled edge; but it can also be readily adapted to other styles of frames. To hold the photograph or picture against the glass I take a flat sheet of metal or other suitable substance of the size required, and I so bend over two of the edges opposite to one another that the said sheet of metal or other substance will slide over two of the edges of the glass, and so hold the photograph or picture securely against the back of the glass through which the photograph or picture is seen. The edges so bent over, being seen when the photograph or picture is looked at through the glass, are not necessarily left visible along the whole of those sides of the frame, but the edges so turned over may be in parts cut away, provided enough of them is left to hold well on to the edges of the glass. I also vary the shape of the metal or other substance where it is turned over in such way as to make it ornamental. The frame thus made stands by means of a projecting strut or foot attached to its back in the ordinary way in which a foot or strut is attached.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
March 18	Bolton Club......................	The Studio, Chancery-lane.
,, 19	Photographic Club	Anderton's Hotel, Fleet-street.
,, 20	London and Provincial	Mason's Hall, Basinghall-street.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

The ordinary monthly meeting of this Society was held at the Gallery of the Royal Society of Painters in Water-Colours, 5a, Pall Mall East, on Tuesday evening, the 11th instant,—Mr. James Glaisher, F.R.S., F.R.A.S., President, in the chair.

The minutes of the last meeting having been read and approved,

The Chairman read a letter from Dr. Eder, expressing his satisfaction at having received the progress medal of the Society.

Mr. George Murray was proposed as a member of the Society and duly elected.

Captain Abney then read a paper, entitled *Illumination of the Dark Room and Some Optical Experiments.* He said that it would appear that M. Claudet was the first to employ coloured light for affording illumination for photographic manipulations, the photographic laboratory having been apparently, before 1844, literally a "dark room." The subject of various media for modifying the colour of light had recently been discussed, and he (the speaker) had been experimenting in the matter like others. At the last meeting of the Society he had brought some samples of what he supposed to be canary medium, and showed the results obtained with them. The samples were made by coating glass with a gelatine emulsion of chromate of lead. This gave a very good modification of canary medium. Using this medium he had obtained in three and a-half minutes a fully-exposed transparency by the light of a candle, the negative and plate being held a foot away from it. The illumination was brilliant. With an orange paper, which was shown, he had got but the faintest impression after five minutes' exposure. Since then he had experimented with the true canary medium. The paper was very thick. He (Captain Abney) here exhibited a lantern—one side of which was coated with canary medium, another with orange paper, whilst the third consisted of a piece of stained red glass. He then described a set of photometrical experiments, whereby he had concluded that the amounts of visual light given by the three sides bore the following ratios:—Canary medium, 1; orange paper, $1\frac{1}{2}$; stained red, $4\frac{1}{2}$.

Mr. C. Ray Woods had repeated the experiments, and had brought out the ratios as—canary medium, 1; orange paper, 1·86; stained red, 4·9.

Mr. J. Cadett had brought them out—canary medium, 1; orange paper 1·39; stained red glass, 2·70. The variations in these results showed that the eyes of different persons were not sensitive in a like ratio to different colours of light. With a piece of tissue paper in front of the stained glass the light given still bore to that through the canary medium the ratio of 2·93 to 1. An exposure of a minute and a-half at a certain distance from the canary medium or the orange paper gave an image, whilst there was none through the stained red. It was, therefore, evident that the red was the best. Canary medium was better than he had expected with candle light, but with daylight was not so good as the orange. A set of photographs of the spectra obtained through the various media were shown by the lantern.

Captain Abney could not recommend the use of green glass, as it only cut off such rays as were harmless. In conclusion, Captain Abney said he had no bias either one way or another. He would have no hesitation in using certain canary media for development, but would not prepare very sensitive plates by the light got through them. The red-stained glass he considered much better, and he would use a large quantity of the light filtered through it.

Mr. W. E. Debenham said that Captain Abney talked of the question as one recently reopened, and that as he (Mr. Debenham) had reopened it he would say a few words. The results which he had obtained he considered of some importance. He thought that with canary medium far more light having action on a sensitive plate was cut off than by the orange paper shown, by two thicknesses of ruby films, or by almost any ruby fabric, whilst the same amount of illumination was given. Some time ago he had made experiments in his own room. He had found red a very unsatisfactory colour to work by, and had tried strips of different-coloured glass, and had simultaneously exposed plates to the light passing through them. He found that those which gave the best light with the least photographic effect were a combination of light yellowish-green glass and pale yellow paper. Some of his friends had fitted up their rooms with light given by these media, and the result had been exceedingly satisfactory. The light was less fatiguing to the eye, and more satisfactory and safe in use than a red light. Suppose that if the three lights—red, orange, and yellow—each produced the same visual light, it was desirable to use that which gave the least photographic action. Suppose they gave the same photographic action, it was desirable to use one which gave most visual light. He did not lay great stress on the green glass. He used it because if he superimposed several layers of yellow medium he got a red light, or at least an orange one. The green glass reduced the light very little. Mr. Cowan had shown a lantern which demonstrated this—one half having green glass, the others not. He had not based his experiments on the results of spectrum work, because he found there was considerable divergence in the opinions of those who made spectrum work a study as to the relative photographic powers of different parts of the spectrum. He based his results on practical experiments with various media, and he had come to the conclusion that with either orange or yellow media he got less photographic action with the same visual power than with red, whilst yellow was the more pleasant of the two first-mentioned colours by which to work.

Mr. C. Ray Woods had tried some experiments. He thought there was very little to choose between orange paper and canary medium. He had pointed out at a technical meeting that cathedral green glass was of little value, and had shown a better kind. On examining the lamp shown by Mr. Cowan with a pocket spectroscope he had seen a certain amount of blue in the light. The reason why this question had come up so often was that photographers had used ruby glass instead of red stained. They had proved the light very unsafe, and had found it necessary to block out a great part of it to get safety. He (Mr. Woods) thought red light was comfortable to work by, but this might be peculiar to himself. He considered the injurious effect of dark room work to the eye was not due to the colour but to the rapid passing from a very dull to a bright light.

Mr. John Spiller recommended the use of aurine in the form of a varnish spread on glass plates. It was very effectual, and it should be considered that from a merely physical point of view there was objection to an emulsion in which the particles were always of measurable size.

Mr. A. Cowan felt inclined to give his opinion in favour of the canary medium. He had seen extraordinarily quick plates prepared in brilliant light which was procured through canary medium. One of these was afterwards exposed for twenty minutes to the light and was not fogged. The green glass and yellow paper had also given very good results, but he did not lay much stress on the green glass.

Mr. Debenham said there was no such thing as cathedral green glass. The term "cathedral" simply applied to the roughish surface of the glass, which could be had of all shades. He had spoken of "green cathedral glass." He used a yellowish-green. Mr. Woods had spoken of seeing blue by the spectroscope in the light he recommended; but as sensitive plates had been exposed close to the light for fifteen minutes without a developable image being produced, whereas five seconds close to a ruby light had procured an effect, this was of little consequence. As to the injurious effects of ruby light to the eye he had the testimony of Mr. H. Harben, who had found that after two hours' work in red light he was quite unable to read, whilst after many hours' work with pale yellow light he was.

Mr. Herbert B. Berkeley mentioned that, in 1877 or 1878, Mr. Henry Cooper had suggested the use of green and yellow glass for dark-room illumination.

Mr. Ince said that the evil effects produced by the sudden change from dull to bright light might be greatly reduced by using coloured glasses when out of the dark room.

Mr. W. Ackland, being called upon by the Chairman, said if many were examined there would be discovered a much greater variation in the sensitiveness of the eye to different colours than Captain Abney had discovered. He knew of many cases where distinct harm to the eyesight had come from working in ruby light. He now used pale yellow light in his dark room, and recommended it to every one.

Mr. W. S. Bird said there certainly must be a discrepancy somewhere, and thought it might arise from a want of absolute knowledge of the chemical effects of the spectrum. He mentioned that horses kept in very dark stables turned blind. This was simply from the rapid transition from dull to bright light and showed that the ill effects occurred apart from colour.

Captain Abney asked Mr. Ackland whether he considered it to be the red colour of the light in the dark room or simply the strains on the eyes which produced ill effects.

Mr. Ackland was not prepared to say.

Captain Abney objected to aurine that unless the coating were thick a trace of violet light penetrated. He had not stated that canary medium was not safe, but more light came through orange paper or stained glass with the same amount of photographic effect. Ruby glass was not safe, as it lets through blue light. He thought experimentalists on the chemical effects of the spectrum were pretty well agreed.

The Chairman said the experiments could not fail to lead to good results. He proposed a vote of thanks to Captain Abney which was carried by acclamation. He (the Chairman) read a communication from Mr. Jabez Hughes, stating he was seriously ill.

It was announced that the next technical meeting would take place on Tuesday, the 25th instant, when there would be an exhibition by lanterns of slides prepared by various methods.

The meeting was then adjourned till April 8th.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

A meeting of this Society was held at the Rooms of the Society of Arts, John-street, Adelphi, on Thursday, the 6th instant,—the Rev. F. F. Statham, M.A., occupying the chair. The minutes of the last meeting having been read and approved,

The Chairman announced that Mr. Macbeth had awarded the medal for the best picture of those exhibited by members to Mr. F. A. Bridge for a picture entitled *River View*. The pictures exhibited would be kept in the Society's album, as also would Mr. Macbeth's letter, which was very instructive. He (the Chairman) asked if any members had tried the canary medium distributed at the last meeting.

Mr. A. Cowan could speak very highly of canary medium. He had recently seen Mr. W. Cobb's dark room, which was about twelve feet long, and which was lighted by one bat's-wing burner behind one thickness of canary medium. The light was brilliant, but a plate was not fogged at the further end of the room by an exposure of twenty-two minutes.

The discussion as to whether ready-sensitised paper gave prints more or less permanent than ordinary paper should have been taken up at this stage, but it was decided to postpone it till after Mr. Dunmore had read his communication, as the subjects were so similar they might be discussed together.

Mr. E. Dunmore then read his paper on *Old Photographs*. [See page 169.]

The Chairman said the subject would stand even more than Mr. Dunmore had read on it. It was a useful one, and he thought it would be particularly beneficial if failures were considered, as then photographers might learn what to avoid. Mr Dunmore had laid great stress on the matter of permanency, and certainly some of the specimens appeared to prove that permanency was possible. They should not lose sight of the fact that they had now better machinery and appliances than they had some years ago, and that by this might be explained any superiority to be seen in photographs of the present day over those of the past. He hoped that different processes would be represented. The Society once had a committee of experimentalists who tried various processes and reported on them. He had brought a few specimens of different processes—amongst others a carbon print by Mr. Johnston; also a few specimens of wax-printing and some chromolithographic prints. He proposed a cordial vote of thanks to Mr. Dunmore. This being passed,

Mr. E. W. Foxlee said he had brought down a few old prints. They had been in a very good state of preservation two years ago, but since then had been standing against a damp wall, and had suffered somewhat thereby. One was on salted paper taken in 1854, the toning bath being that known as the *sel d'or*. A pair of stereoscopic views were shown to demonstrate the fact that the density of a negative has much to do with the permanence of the print. One of the negatives had been denser than the others, and the half of the print which bore the impressions from the dense negative was in good condition, whilst the other had faded. Specimens were shown demonstrating that prints, both mounted and unmounted, went faster at the edges than at the centre. One print which had been toned with sulphur, no gold being present, was found to be in good condition.

Mr. F. York showed a print taken in 1856, which was growing very yellow. One that had been mounted over another print showed the part round the edge which was in contact with the mount to be faded, whilst that over the print was not. This seemed to point to the fact that something in the paper of the mount tended to fading.

Mr. T. Parkinson (Vice-President of the Bolton Photographic Society) had prints toned both by the *sel d'or* bath and in the hyposulphite bath which had kept well. He thought prints on the paper prepared at the present day would not keep so well as those on the paper prepared some years ago.

Mr. W. M. Ayres exhibited prints taken in 1851, which were in fair condition. He also showed prints on double-albumenised paper taken many years since. He thought prints mounted on glass with isinglass, and with paper pasted on the back of them, were permanent.

Mr. F. Howard remarked, with regard to prints fading first at the edges, that when they were kept in books the edges were more subject to atmospheric influences. When a photograph was mounted, carefully framed, and placed in a dry room, fading took place equally all over it.

Mr. Foxlee said another theory of fading at the edges was that in mounting the print was pressed into closer contact with the mount at the edges than in the centre.

Mr. Ayres remarked that mounted prints faded more rapidly than unmounted ones.

Mr. H. P. Robinson, of Tunbridge Wells, sent a portfolio of prints taken in 1855, 1856, and 1857.

Mr. Foxlee said that the most permanent prints were taken on very slightly-albumenised paper.

The Chairman thought this might be attributable to galvanic action, and cited the case of iron rails which were eaten away at the contact with solder, and referred also to the sheathing of ships. He said there was an American photographic journal of 1856 with photographic illustrations which were very much faded.

Mr. W. M. Ashman said that the effect of time was to diminish the lustre of the surface of prints. He instanced some prints which had been in a show-case for only a few months, the surface of which had deteriorated very much.

Mr. Foxlee believed that this was due to alternate condensation of vapour on the prints and the re-evaporation of it. In 1856 pure albumen was seldom used for paper. Water was always mixed with it.

Mr. York could not see why ready-sensitised paper should give prints less permanent than other paper. The silver salt was the same, and the citric acid could be neutralised in the last washing water before toning. Some time ago it was stated that the silver sensitising bath might be used at half strength by adding nitrate of soda to it. Two prints produced on paper—one sensitised with a sixty-grain silver bath, the other on a bath of thirty grains of silver and thirty grains of nitrate of soda—showed great difference in permanency. The prints on the sixty-grain bath lasted much better than those on the other; he, therefore, thought it important to use a strong bath. He wished to ask Mr. Dunmore in what did a solution of hyposulphite of soda deteriorate.

Mr. Dunmore said that the hyposulphite turned to sulphite if it stood long.

Mr. York suggested that the prints sent in for competition should be each marked to indicate whether or not ready-sensitised paper had been used in their production, and that thus in time the question would be solved.

Mr. Dunmore said that many of the prints sent round had been sensitised in a bath of forty grains of silver and forty grains of nitrate of soda

Mr. York stated that there was a great difference between forty grains and thirty grains. Ready-sensitised papers were generally blotted off and not drained, so that there would be less free silver nitrate; and for that reason the image might be less permanent.

Mr. Dunmore had prints done on Durand's paper when it first came out some fifteen or sixteen years ago, and they had not faded.

Mr. T. Bolas said the question was a difficult one, and required more time than could be devoted to it in one evening.

Mr. Ayres considered that the surface of the paper was injured by the citric acid in ready-sensitised paper.

Mr. Parkinson thought that ready-sensitised paper gave less permanent prints than other paper.

Mr. W. K. Burton said that at anyrate in the case of prints on ready-sensitised paper there was a difference in the permanence according to whether or not the free silver was well washed out of the prints. If it were not they toned very quickly, but lost part of their tone in the fixing bath and faded in a few years.

Mr. Foxlee agreed with Mr. York that the more silver there was in the paper and the more of this there was reduced in the print the more permanent was the image. It was, therefore, necessary, in comparing the two kinds of paper, to take into consideration the amount of silver contained. Probably Durand's paper was once sensitised on a stronger bath than at the present day. In 1856 a ninety-grain bath was frequently used.

Mr. Ayres had found that a few sheets of Durand's paper spoiled a toning bath containing forty-two grains of gold chloride.

Mr. Mackay said that there were such great differences between different kinds of ready-sensitised paper that it was as impossible to class them all under one head as it would be to class ready-sensitised paper and that prepared in the ordinary way together. Some ready-sensitised papers printed red and others purple.

The conversation here became general, and, after a vote of thanks to the Chairman, the meeting was adjourned.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on Thursday, the 6th instant, Mr. J. Barker occupied the chair.

Mr. F. W. Hart showed an arrangement of an Argand gas burner enclosed in a glass tube of about two inches larger diameter than the chimney. This tube was closed at the bottom, so that the air for feeding the flame passed between the two glass surfaces and became strongly heated before reaching the flame. The glass chimney was continued by an iron tube, so that the products of combustion could be led away. It was considered that it could be usefully employed in photographic dark and work rooms, as it would ventilate instead of vitiating them.

Mr. J. B. B. Wellington exhibited a lantern with yellow paper and green glass similar to the one previously presented by Mr. A. Cowan, except that it was made of wood, which was a material that many could use who were not experienced in metal working. There was one point in connection with it that would be sometimes a convenience—the front slid in a groove and could be easily opened, and the bare flame utilised when printing transparencies.

Mr. Hart inquired whether there was any difference in the safety of the light when the glass or the paper was outside.

Mr. Wellington thought not.

Mr. A. L. Henderson showed a changing-box that was made for him by Messrs. Dale and Hare, on the principle which has been previously described. Certain alterations had, however, been made in accordance with his (Mr. Henderson's) instructions. The plates would only work in one direction, and, therefore, could not be put backwards by carelessly turning the box the wrong way round. There was also—and in place of the small piece of ruby glass through which the number of the slide was examined, and which might be thought in a bright light to be the cause of some fogging—a contrivance by which the plate in being changed moved an index, visible on the outside and marked with the number of the plate ready for exposure.

Mr. Hare thought Mr. Henderson's alteration complicated the construction, and that with the original formation there was no danger of the evils to which reference had been made.

Mr. W. E. Debenham considered Mr. Henderson's alterations an ingenious improvement.

Mr. Wellington showed some negatives on plates coated with an unwashed emulsion. There were mottled markings on these plates, which, however, could be removed (as shown on the half of a plate that was exhibited) by dilute hydrochloric acid.

Mr. Henderson thought the action of the hydrochloric acid was partly to swell the gelatine, and that it was by this action that the markings had been removed.

Some discussion then arose on the subject of polarised light.

Mr. A. Haddon recommended the work of Mr. Lewis Wright on the subject to those who wished to make a study of it.

In obedience to the strongly-expressed wish of the members Mr. C. Darker promised to give another demonstration on the subject of polarised light, dealing particularly with the scientific side of the question.

AMATEUR PHOTOGRAPHIC ASSOCIATION.

A council meeting of this Society was held on Thursday, the 28th ult., at 12, York-place, Portman-square,—Lieutenant-General the Right Hon. the Lord de Ros in the chair. The minutes of the last meeting having been read and confirmed,

The following members were elected:—Major-General C. F. Arbuckle, R.A., Sir. W. T. Thompson, C.B., Lieut.-Colonel S. Micholl, Messrs. P. H. Emerson, B.A., M.R.C.S., H. R. Moiser, F.G.S., W. H. Sedgewick, E. G. Burls, L. F. Reichling, W. D. James, T. H. R. Salmon, H. E. White, M.A., F. C. Borckhardt, J. T. Black, R. G. Bellringer, and C. A. Gilder.

The Secretary then laid before the meeting the following prizes, which had been awarded at the annual meeting:—First prize, an oil-painting in frame, by Carl Frisch, Mr. R. Leventhorpe. Silver goblet, Mr. S. Norman. Silver goblet, Mr. W. S. Hobson. Water-colour drawing in frame, Mr. R. O. Milne. Oil-painting in frame, by J. W. Waterhouse, Mrs. Abbott. Silver goblet, Mr. W. Muller. Silver goblet, Mr. G. Western. Water-colour drawing in frame, Mr W. Adcock. Water-colour drawing in frame, Mr. P. Gunyon. Landscape album, Mr. T. Brownrigg. Portrait album, Mr. F. S. Schwabe. Portrait album, Mr. G. Brook, Jun.

These prizes were approved, and the Secretary was directed to deliver them to the members to whom they had been accorded.

A vote of thanks to the Chairman was passed, having been proposed by Mr. Glaisher and seconded by Captain Lewis.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The ordinary meeting of this Society was held at the Mechanics' Institution, on the 14th ultimo,—Mr. J. Pollitt, President, in the chair. Messrs. Barlow, Lomas, and Hadfield were elected members of the Society.

The Chairman referred to the relative plates exhibited at the previous meeting by Mr. Chilton, showing insensitive marks in pictures, and said he thought the marks were caused by the precipitation of Ag Br to the edges of the plates.

Mr. R. Atherton said he had met with a similar trouble, but had traced the defect to the emulsion being short of gelatine.

Mr. Smith brought some plates showing similar markings, which, in his opinion, were caused by imperfect removal of the decomposition salts.

Mr. J. Schofield contended that this explanation could not be correct, or the marks would occur all over the plate. He further stated, in support of his belief (expressed at the previous meeting), that faulty drying arrangements were the cause, and that he had made an arrangement in his drying-box which permitted the plates to be inspected during drying, and was confirmed in his opinion.

A somewhat lengthy discussion ensued on the same subject, Messrs. Schofield, Atherton, Chilton, and Smith advocating their own theories.

Mr. J. W. Leigh showed a negative developed by the light of ordinary gaslight screened with canary medium, and decided to adopt this illuminating medium in his dark room. The negative was perfectly clean.

Mr. Richton read a paper *On Swing Backs* versus *Rising Fronts*, illustrating his remarks by means of an ingenious model of a camera in section. The paper was warmly received.

The Chairman expressed his pleasure in hearing the communication, and complimented Mr. Richton on his ingenuity in designing the model. He stated that his objection to the swing-backs was that he thought that placing the plate at too great an angle to the axis of the lens must have a distorting effect, and showed a photograph of a rectangular figure, using swing-backs and then with rising-front, thus proving by measurement that there was some distortion arising from the use of swing-backs.

Mr. J. Y. McKellan advocated a swing-front as doing all that could be done with swing-backs without any distortion.

Mr. Schofield considered that the best way was to combine the rising-front and swing-backs.

Mr. Watts expressed himself much pleased with Mr. Richton's paper, and moved a vote of thanks. Mr. Blakely seconded the same, which was carried.

The Chairman suggested that, as the subject had evidently excited a good deal of interest, members should study the matter before the next meeting.

Mr. Watts was requested to read a supplementary paper, and the meeting was adjourned.

LEEDS PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held on Thursday, the 6th instant, in the large lecture hall of the Leeds Philosophical and Literary Society. The hall was well filled by the members and their friends. In the absence of the President, Mr. J. W. Ramsden, Vice-President, occupied the chair. After the transaction of a little formal business the meeting proceeded to the election of new members, and Messrs. Law, Lloyd, Whitehead, and Professor Rücker were declared duly elected.

The Chairman then called upon Mr. W. Teasdale to conduct the lantern exhibition.

Mr. Teasdale expressed his pleasure at seeing so many members and friends present, and also at the large number of slides which had been sent in for exhibition. Lantern work was new to most of the members; but the slides which he and the Hon. Secretary had had the opportunity of examining were very good, and quite equal to those generally seen. In selecting from such a large number preference would be given to those produced by the members, and if time allowed the very fine slides by professional makers would be passed through.

Mr. Pocklington exhibited a series of fourteen slides, taken on gelatino-bromide plates, and illustrating the various effects produced by using such developers as ferrous oxalate and ammonium chloride, hydrokinone and carbonate of soda, pyro. and carbonate of soda, ferrous oxalate and nitrate of potash, &c.

Mr. H. Rodwell showed transparencies on gelatino-bromide plates developed with pyro. and toned with mercury.

Mr. Thompson exhibited an instantaneous view of a tramway car.

The Chairman showed slides on gelatino-bromide plates reduced from 8×10 negatives, some of which were taken thirty years ago. He also exhibited two slides of each subject, one being developed with tartaric acid and ferrous oxalate and the other with pyro. and pearl-ash—fifteen grains of the latter to one ounce of water.

The Hon. Secretary presented a series of slides on gelatino-bromo-iodide plates and gelatino-chloride plates (own make), showing on both bromide and chloride plates the difference in tone, varying from blue black to bright red, that could be obtained by variations in the exposure and development, the exposures to the same light varying from four seconds to forty-five minutes.

Mr. Kidson showed transparencies on gelatino-bromide (Ramsden's) plates.

Mr. W. Denham exhibited a number of very fine transparencies—shipping and landscapes in the Isle of Man—on Ramsden's, Nelson's, and Cowan's plates.

Mr. W. Teasdale presented some slides on gelatino-bromide plates, and also on plates by Chapman, Cowan, and England. He (Mr. Teasdale) also exhibited transparencies of Muybridge's animals in motion, and a very fine selection of slides by the Woodbury process.

Mr. J. W. Reffitt showed some very fine instantaneous views of *Swans, Boy Sailing Boat*, &c., and a number of continental slides.

The lanterns (oxyhydrogen), fitted with Dallmeyer's lenses, were lent by Messrs. Reynolds and Branson, and were manipulated by Mr. White, a member of the Society.

The meeting was then adjourned.

DUNDEE AND EAST OF SCOTLAND PHOTOGRAPHIC ASSOCIATION.

The sixth monthly meeting of this Society was held in Lamb's Hotel, Reform-street, on Thursday, the 6th instant,—Mr. J. C. Cox, President, in the chair. The minutes having been read and approved,

Dr. J. K. Tulloch then proceeded to make some remarks on *Halation*. [See page 167.] A lively discussion followed, and Dr. Tulloch promised to extend his experiments and give some more particulars at the next meeting.

The adjourned discussion on Dr. Tulloch's previous paper, *Shortcomings of Photography*, was then resumed, and a very animated discussion ensued.

The nomination of office-bearers for the ensuing season was then proceeded with, and it was arranged to ballot the names at next meeting.

The question-box contained the query—"Whether is collodion or varnish the best protector of gelatine plates?" The inquirer was recommended to use a coating of each, applying the collodion first and the varnish above it.

The subject for next monthly meeting was announced as *Still Life*.

It was arranged to hold a competition for lantern slides within a fortnight, each member to send only three slides for *competition*, although at liberty to send as many as he chose for exhibition.

Mr. G. D. Macdougald exhibited his new instantaneous lantern slide carrier, which, by an ingenious but simple arrangement, instantly substitutes one slide for another.

A vote of thanks to the Chairman brought the meeting to a close.

BOLTON PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held on Thursday, the 6th instant, when there was a very fair attendance. Mr. Heaton was elected a member of the Society.

It was decided that the third annual open meeting be held in April next, and the evening was spent in discussing the arrangements.

Owing to the unavoidable absence of Mr. R. Harwood, the usual lantern exhibition was not given.

SHEFFIELD PHOTOGRAPHIC SOCIETY.

The regular monthly meeting of the above Society was held in the Freemasons' Hall, on Tuesday, the 4th instant,—Mr. J. H. Rawson occupying the chair. There was a very large attendance.

Mr. W. B. Hadfield introduced the subject of lantern slides, and exposed and developed several plates before the members. He succeeded in producing by contact printing, by gas and candle light, several good transparencies on Chapman's gelatino-albumen plates. He also exhibited a variety of slides made at home, both by contact printing and through the camera.

Mr. J. Turner exhibited some excellent slides made on ordinary gelatine plates developed by the alkaline pyro.

Mr. W. Dakin brought a brilliant transparency developed with pyro., and gave very practical arguments in support of the ordinary pyro. developer being all that was necessary to produce perfect transparencies. He suggested that the use of the alum, acid, and iron clearing and intensifying solution was very valuable in slide making.

Mr. Ainley also gave some useful hints in the exposing of transparencies, and argued that a long exposure to a weak light was much better than a short exposure to a strong light, and in favour of a quick development. Many other members took part in the discussion.

Mr. Dickenson brought an excellent burnisher of his own make, which was highly commended for its construction and cheapness.

Messrs. Nillington and Walker were elected members of the Society. After further discussion and various announcements relating to the monthly competitions, a most interesting and practical meeting was brought to a close.

NORTH STAFFORDSHIRE PHOTOGRAPHIC ASSOCIATION.

The monthly meeting of this Society was held at Hanley, on Wednesday the 5th instant,—Mr. C. Alfieri in the chair.

The Chairman exhibited an instantaneous shutter made by himself for a stereoscopic camera, and constructed to work behind the lenses; also, some dark slides his own make, a novel feature in them being that each slide held four quarter-plates, each of which could be exposed separately.

On Wednesday, the 12th instant, Mr. Alfieri invited a number of the members to his residence at Northwood, and placed a good lantern and his laboratory at the service of those present. He proceeded to give a demonstration of a method of enlarging upon Messrs. Goodall and Steven's enamel paper, plain paper, and opals. Several enlargements were successfully made from half- and quarter-plate negatives, a large three-wick burner being used; the exposures given varied from one to three minutes. The resulting pictures were developed with M. Audra's modification of the ferrous oxalate developer. The pictures, and the simple process by which they were produced, were much admired, especially a vignetted enlargement of a child's head on opal from a negative taken by Mr. Allison, six enlargements having been made without a failure in any case.

The members congratulated Mr. Alfieri upon his skill, and Messrs. Goodall and Steven upon the high quality of the materials supplied. All the pictures were remarkable for freedom from any defect and for the preserved purity of the whites.

A vote of thanks was passed to Mr. Alfieri for his kindness.

It was resolved to engage a suitable room in Hanley, where chemicals and apparatus might be stored, and demonstrations of any kind given.

The Hon. Secretary offered the use of his studio and dark room to any of the members during the coming summer.

After some interesting conversation upon technical topics and thanking their host the meeting separated.

Correspondence.

March Meeting of the Photographic Society of France.—M. Sauter on Development of Gelatino-bromide of Silver Emulsions.—M. Boscher and the Electric Light.—Instantaneous Photography in the Studio.—Rapid Shutter with Electric Trigger.—A New Stretcher for Films in the Dark Slide.—Presentation by Professor Stebbing of Reconstructed Negatives by Means of Transparent Films.—Presentation of Microbes in Tuberculose Microscopic Preparations by MM. Perrot de Chaumeux and Londe.—M. Vidal's New Stand.—M. Gauthier-Villars' New Photographic Publications.—M. Balagny's New Transparent Paper Films.—Obernetter's Etching Process.

The monthly meeting of the Photographic Society of France was held on Friday evening last, the 7th instant,—M. Péligot in the chair.

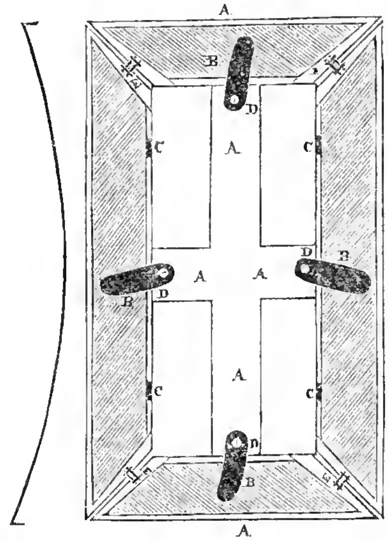
M. Sauter, of Geneva, sent a communication to the Society on the development of gelatino-bromide plates. He said that whatever the exposure a good negative may be obtained by careful development. A proof was sent round, of which the negative had been over-exposed at least four times. He had so controlled the development as to get a good proof. It appears that he plunges the over-exposed plate into a ten-per-cent. solution of potassium bromide. The plate is then developed in the ordinary ferrous oxalate bath, to which has been added a little citric acid. A few drops of a five-per-cent. solution is all that is necessary. M. Sauter appears to have succeeded in obtaining great control in developing—probably because he has been experimenting upon plates which he has over-exposed from one to four times. Thus he has been able to know how much restraining solution to employ to get a certain result; but it may be very empirical to try it upon plates of which the proper exposure is not known, for if it act well upon over-exposed plates it probably would have the opposite result upon under-exposed ones.

M. Boscher advocated the use of the electric light for portraiture. He employs, he says, with success, four arc lights, the carbons of which are burnt in proximity to marble pillars. A number of proofs (*carte* album) were passed round. They did not secure the approval of the members, as they were inferior to those obtained by the orb of day, and the remark was passed that it was of no avail in placing electricity in competition with our old friend the Sun if results were not better, or at least equal, to what was obtained by his agency, &c.

M. Haincque de St. Senoch (one of our most enthusiastic amateurs) has been experimenting in order to obtain instantaneous portraits in his studio. He presented an album to the Society, in which is portrayed the image of a clown going through all his fantastic and ludicrously-wild antics. Summersaults and all his Merry-Andrew tricks were faithfully seized by the photographic plate. The album showed a decided success, and the author was complimented by his colleagues for his perseverance.

M. Trevaux presented an instantaneous shutter with an electric trigger. A small electrical battery is carried in the pocket, and is connected by means of wires to the trigger. M. Trevaux said that this system was far preferable to the air-ball and tube, as the latter required complicated fillings in the interior, which, when put in motion by the pressure of the hand upon the ball, caused the apparatus to vibrate, whereas the electric trigger gave none. There is nothing new here so far as I can see. A good "dodge," however, is that when the electric current is not wanted the battery is turned upside down and no electricity is generated.

M. l'Abbé Raboisson, in his voyage to Africa, employed photography, and in order to make his luggage as light as possible he employed films instead of plates. To work the same without the aid of a fixed glass plate, and to have them perfectly flat in the dark slides, he invented a stretcher which did good service. The stretcher is made of thin brass, exactly of the size of the film required. The film must be cut to a quarter of an inch larger than the frame. The film is laid upon the table, and the stretcher is placed upon it. The edges of the paper touch the film but the middle does not, as the edges form a curve. We shall soon perceive the object of this. To fix the film in the stretcher one of the buttons D is turned round, the shutter B is lifted up, and the quarter of an inch of film is brought over. The shutter B



A, thin brass frame. B, four brass shutters. C, hinges fastening shutters to frame A. D, buttons keeping the shutters B in close contact with frame A. E, sliding bolts to keep corners of frame A in their place.

is dropped down upon it, the button is put in its place, and so on with the three other sides of the film. The stretcher is placed in the dark slide, the back of which, coming in contact with the centre of the stretcher, cannot be shut without a certain pressure being given. This pressure forces the stretcher to become flat, and thus the frame A gains about one-eighth of an inch or more in length and width, and the film is stretched like the head of a drum. This apparatus is very ingenious, but has two faults—first, being heavy and expensive; and second, requiring films larger than the proof obtained.

The simple method adopted by M. Vidal, of putting diachylon plaster upon the two sides of a sheet of ebonite for double frames, is both easy and cheap, and offers no difficulty whatever. After exposure the exposed film is torn from the sticky surface and another put on in its stead. If the diachylon become too hard it can be softened by a little benzoline, and if too soft a little French chalk is sifted over it.

I had the honour to present the Society with some film negatives which had been obtained from paper prints. The object of the presentation was to show the ease and facility photographers now have to make reproductions of valuable negatives. A good print is obtained from a negative, and it can be retouched, clouds put in, &c., if the view be a landscape. The print is placed in a printing-frame, image upwards, and the sensitised side of the film is put upon it. The padding is placed in the frame, closed, and firmly screwed up with iron screws, if possible. The more pressure the better will be the results. The frame is now exposed to gaslight from five to ten seconds. The light goes through the back of the positive print, the paper of which acts as a screen of ground glass. When developed a magnificent negative is obtained—quite as good as, if not better than, the original one. The preservation of film negatives is a very easy matter. Thousands can be laid one upon the other without any fear of their weight breaking down the house or their being destroyed by any other agency than damp. This, indeed, can be diminished to a minimum by coating the film negatives with collodion.

M. Jubert forwarded a long letter to the Society on the composition of commercial bromides.

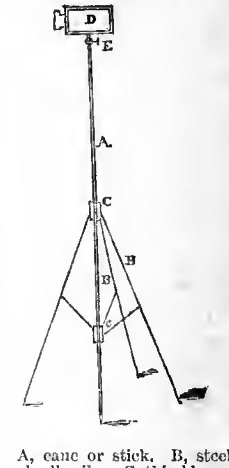
The Chairman said as it was very long it could not be read that evening, and gave instructions that it should be inserted in the *Bulletin*. A scientific analysis of the different bromides as an easy means of discovering frauds would be a great boon to emulsion makers, as adulteration is not unknown in these most necessary chemicals.

MM. Perrot de Chaumeux and Londe have made some very interesting experiments, in a medical point of view, on the microbes of the tuberculosis. The expectorations of persons afflicted with the "phthisic pulmonaire" have been photomicrographed, and the animalcules were clearly seen by enlarging the image by projecting it upon the screen.

M. Mourlot exhibited a new substance partaking of the qualities of india-rubber and gutta-percha, at about half the price. This substance will be of great service in making trays for baths and different solutions used in photographic manipulations.

The Secretary announced that the yearly banquet of the Society would take place on Saturday, the 15th instant, and that the Society would welcome the members of any foreign society presented by one of the members.

M. Vidal completed his presentation of a pocket apparatus by exhibiting a very light stand for the same. The stand is composed of a light stick, like the handle of an umbrella. The resemblance goes further, as in the centre of the stick is attached to a thimble three steel umbrella ribs. These ribs, when opened and placed upon the ground, form a triangle, the stick going through. The ring or thimble at their point of junction falls upon the ground, and, having a steel point, it penetrates a little into the soil. The three ribs now keep it perfectly steady, and, notwithstanding its extreme lightness, the apparatus when put upon its top does not vibrate. An ordinary tripod stand has three points of support in the ground. M. Vidal's has four—the three legs and the centre stick—which give solidity to the whole. The camera-stand goes into an ordinary hollow walking-stick. M. Vidal was highly complimented. That gentleman then passed round a number of negatives and paper positives obtained by his pocket camera. The large negatives were, he said, obtained upon Professor Stebbing's new expanding films, manufactured at his request for his pocket camera. The small ones were upon M. Balagny's new transparent paper films. Both gave good results, but M. Vidal preferred the expanding films, as the image was much larger.



A, cane or stick. B, steel umbrella ribs. C, thimbles or rings to which are attached the ribs. D, pocket camera. E, universal socket joint.

M. Gauthier-Villars, the well-known editor of scientific books, has just published two new works which will render great service to photographers and amateurs. One, translated from the English, is Mr. Arnold Spiller's *Twelve Lessons on Elementary Photographic Chemistry*, and the other a translation from the German of the second edition of *The Theory and Practice of the Gelatino-Bromide of Silver Process*, by Dr. J. M. Eder. The name of Dr. Eder is well known to the readers of The British Journal of Photography, so it would be superfluous to speak of the value of the work, because Dr. Eder has given proof of his remarkable activity, high intelligence, and deep research—all of which he has devoted to the progress of the photographic art. I can only counsel all who practice photography to have this interesting and scientific work in their laboratories. M. Gauthier-Villars must also be commended for placing this valuable and instructive book in the hands of all who understand the French language.

M. Balagny—another of our distinguished amateurs—presented a new gelatino-bromide of silver film supported upon paper. He names it—"*Papier transparent a pellicule reversible au gelatino-bromure d'argent.*" The paper film is exposed in the camera or employed to obtain positives by transparency. The emulsion of which it is made is excellent, and the whites are clear and no sign of fog can be detected; it adheres firmly to its proper support and never frills. The development goes on without any difficulty, either by the pyro. ammoniacal or the ferrous oxalate systems. M. Balagny informed the members that the paper when once in the developer has no tendency to roll or curl up, and as the film of gelatino-bromide of silver is very thin the development is rapidly terminated, the negatives or positives obtained being free from faults and very intense. As soon as the hypo. is eliminated the film can be transferred (on either side) upon a sheet of glass or transparent gelatine, or can be made into a transparent film by collodionising the two sides of the film. M. Balagny demonstrated this transfer before the members. One of the most interesting experiments had for its object to obtain film transparencies for the magic lantern. The film is made to leave the paper, and when put upon the glass it has a very pretty, neat appearance, as if it were placed on ground glass. This brings out the positive in all its details, and is caused by the starch paste employed to hold the film upon the paper. For positives this appearance is very harmonious, but for negatives it would not be beneficial. The author explained that by washing the film the paste was dissolved and the film could be made perfectly transparent. M. Balagny then showed how easily stereoscopic pictures could be obtained by his process. He took proofs out of the water, cut them of the proper size, placed them, image downwards, upon the glass plates, and with a squeegee drove out all the water and the air-bells. He then took some dry ones, and the paper left the film with the greatest ease. Some negatives were then shown upon paper, and in order to strengthen or thicken the film a piece of the commercial gelatine films was placed in water and then affixed to the film with the greatest ease. To sum up: when an image is obtained upon this film paper it can be transferred to any object and re-transferred as often as wished for. A great desideratum has been accomplished by M. Balagny by obtaining films which can be printed from on either side. Mechanical printing can now go on at full swing, being no longer fettered by the necessity of turning the negative, &c. Any of the known means of fixing films in the dark slide can be employed, such as glass support, diachylon, and the Abbé Raboisson's new stretcher. Amateurs will be the first to welcome this new paper, which is so precious for those who travel far from their homes. Breakage is no longer to be feared, not to speak of a notable diminution in weight and facility of manipulation. M. Balagny, during his experiment, crushed up a film in his hand. The negative was not injured in the least by this rough treatment. M. Balagny was felicitated for the very great progress he had made and the perfection he had attained in his transparent paper films.

Herr Obernetter's method of engraving plates was discussed. A journal publishing the method as a new discovery has wakened up other inventors. The same process has been worked for years in Manchester, and was patented by Mr. Sachs, in England, on the 11th of February, 1880. Herr Obernetter now employs a new patented process, which consists in coating a sheet of paper with bitumen and gelatine. The back of the paper is bichromated, and then exposed to light under a positive or a negative. The paper is then put into warm water, when the gelatine unacted upon by light swells up and raises with it the coating of bitumen. This washes away, while, on the contrary, the parts acted on by light maintain the bitumen, and an image is thus formed. When dry the paper bearing the bitumen image is pressed upon a block of metal. The back of the paper is damped with perchloride of iron, and this passes through the paper in every part where the reserve of bitumen is absent, eats into the metallic plates, and engraves the image. A more simple process could not have been thought of. I have myself seen this process in full work in this city. E. Stebbing, *Prof.*

25, *Rue des Apennins, Paris, March* 11, 1884.

SINGULAR LUMINOSITY OF THE ARGENTIC-BROMIDE FILM.

To the Editors.

Gentlemen,—I have very carefully read the letter by "A. S." in your last issue, and I can hardly think he means seriously what he seems to say, which, read with my article, amounts to this—that the evolution of a greenish-blue light is the result of the presence of an orange-coloured one.

The theory of complementary colours and the retention of the retina would, no doubt, account for the light I produced being apparently greenish-blue; but "A. S." would seem to go further than this, and say that the existence of one source of light accounts for the production of another. This proposition seems hardly worth combating; but I would ask if it be seriously advanced? Why are such appearances as my "silent discharge" not more common—indeed general—with all using such a very common form of lamp as the two thicknesses of orange paper mentioned? Why should I only have seen them when the disruption was forcible, and not when there was no adhesion of the pieces of paper to the film?—I am, yours, &c., H. H. Cunningham.

Notes and Queries.

S. S. B. asks—"What is the date of Swan's carbon patent, and is it still in force?"——In reply: The patent was obtained on February 29, 1864, and has long since expired.

How can brown tones be obtained in transparencies made by the wet collodion process?—G. Henry.——In reply: An application of a solution of sulphide of potassium will give the tones desired, but this toning agent is a treacherous one.

J. P. T. inquires whether gelatino-bromide plates of English manufacture can be procured in Switzerland—by preference, in Geneva.——If he be about to visit that country he would act prudently in taking out with him a supply of the particular class or make of plates to which he has become accustomed. Perhaps some reader familiar with the state of the plate supply in Switzerland will answer the query.

A New York Citizen.—This correspondent addresses to us a very singular query. He says:—"Is there anything either legally or morally wrong in being a vendor of a photographic process?"——Certainly there is not; but, on the contrary, there *may* be much that is commendable in process-vending. If an individual know of something he believes to be good that would prove beneficial to photographers he would act a rather churlish part in withholding it from them. On common business principles, however, he is not necessarily entitled to give it to them without remuneration. But he is wrong if he show as the result of a certain secret process something not produced by it, and then sells the process under this false impression. This is both morally and legally wrong. Otherwise it is an ordinary business transaction, in which one obtains a sum of money from another for imparting to him certain knowledge of which he was previously ignorant.

A lens in my possession, which hitherto had proved to be as near perfection as any single landscape lens I have yet seen, has during the present winter shown indications of the disintegration of the balsam by which its components are cemented. I have on the advice of a friend exposed it to heat in the expectation of the balsam becoming melted and re-spreading itself between the surfaces. But this result has not followed, although I have heated it by placing it in water not far below boiling-point—in fact, hotter than I could bear when incautiously inserting my fingers. I have tried when thus heated to effect a separation of the lenses by sliding one upon the other, but the cement does not yield to heat. Kindly say how I am to proceed. I have uncemented many lenses, but this one defies my best efforts.—J. A. B.——In reply: Procure a round tin box of sufficient capacity to contain the lens, which place inside, and fill up with benzole, allowing it to stand for one or even two days. The benzole will very slowly penetrate between the lenses and dissolve (or at anyrate soften) the cement, and thus enable them to be separated.

Vita.—This correspondent sends a specimen of his photographic work. His experience is confined to the past twelve months, and his knowledge has been derived exclusively from books. The specimen is not only creditable, but superior to much that not unfrequently emanates from establishments of good reputation.

T. W. A. says:—"I have read with much interest the article on *Polarised Light* in last number, and am induced to inquire if the polarising angle, as existing between the light emerging from the condensers and the intercepting parcel of glass plates, be the definite one we are led to suppose. If 57° be the correct polarising angle, only one portion of the light, and that a very small portion too, will be polarised, seeing that the light is projected forward in a converging beam, not one ray in which is parallel to any other. The angle, therefore, mentioned above cannot be maintained unless for the axis of the emerging and converging beam. If this reasoning be correct, then there is not a very large amount of light lost, in the sense of very little of it becoming polarised?"——In reply: Our correspondent is quite correct in his reasoning. This particular topic was, several years since, brought prominently before the notice of the British Association by the then editor of this Journal, who provided a remedy for the evil. It consisted in interposing a small concave lens in the luminous cone just previous to its impact upon the bundle of glass plates by which it is to be polarised. This has the effect of converting the converging into a parallel beam, every ray of which falls upon the glass plates at the proper angle, improving the effect in a marked degree. After reflection from the polariser the parallel rays are once more rendered convergent by a plano-convex lens, the counterpart of that previously employed in effecting parallelism. But for practical purposes there is a certain degree of latitude allowable in the determination of the angle, and this in some measure compensates for the convergence of the light.

Photographic Piracy.—Samuel Rosenthal, 12, Partridge-court, Houndsditch, was summoned before Sir Thomas S. Owden by Mr. M. B. Huish, Secretary of the Fine Arts Society (Limited), for offering for sale a photographed copy of a painting called *The Return from the Battle of Inkerman*, of which they were the proprietors of the copyright. He was also summoned by Mr. B. Brooks, publisher, 121, Strand, for a similar offence with regard to two pictures of which he held the copyright.—Mr. W. H. Burgess said he was an inquiry agent to the Fine Arts Society, and others. On the 4th instant he was on the City side of London Bridge, when he saw the defendant carrying what appeared to be photographs. Witness asked him to let him look at the pictures, and saw that there were nine photographs which had been pirated from pictures the copyrights of which were vested in different publishers. After mentioning further details, witness added that summonses were granted against the defendant. Witness had communicated with the publishers, and they appeared to press the charge.—Mr. M. B. Huish said that he was the Secretary to the Fine Arts Society. They were the registered proprietors of the picture called *The Return from the Battle of Inkerman*. He did not give the defendent consent to offer photographed copies of that picture for sale. The photograph produced was a copy of that picture.—Mr. B. Brooks said he was a publisher, at 121, Strand. He was the registered proprietor of the copyright of two pictures called respectively, *Can't You Talk?* and *Which do you Like?* He did not give the defendant consent to offer for sale any photographed copies of those pictures. The two photographs produced by Mr. Burgess were copies of his pictures.—Mr. Burgess was re-called, and said that the defendant had given him information which was correct. The man who induced the defendant to sell the photographs also induced him to pawn his goods to pay one-half their value, and they divided the receipts. The makers would not do business on any other terms. He had a wife who was very ill, and they were very poor.—Sir T. S. Owden said he wanted, if he could, to prevent the defendant going to prison. He could fine him £10 on each summons; but if he could not pay it there would be no alternative for it, for he must go to prison.—After conversation on the matter, Sir T. S. Owden fined the defendant 10s. and costs on each summons, with the alternative of five days' imprisonment on each, the terms to be consecutive.—*Standard.*

Exchange Column.

I have a rolling-press, two rollers, $6\frac{1}{2} \times 3$ in. diameter; also, *Bigelow's Album* (with key) *of Lighting and Posing*. Wanted, anything in exchange in photography.—Address, NEWTON, 276, Ribbleton-lane, Preston.

What offers for Ross's No. 2 quick-acting *carte* lens and posing-chair? Wanted, half-plate bellows-body camera and dark tent, portable; difference adjusted.—Address, SULPHITE, 52, Goldsmith-road, Peckham, London, S.E.

What offers for seven valuable books, best works on photography, chemistry, retouching, &c. (list on application); also retouching-desk, and four-wheel dark carriage, suitable for pony?—Address, PROTT, 18, Tacket-street, Ipswich.

I will exchange a quantity of birds (foreign), with three domed aviary (nearly new), made to partition into three separate cages, for good cabinet lens or anything useful in photography.—Address, A. HOLT, Northleigh House, Stowmarket.

I will exchange $2\frac{1}{4}$-inch portrait lens (takes a good cabinet), large waterproof fishing bag, splendid bottom tackle case, both equal to new, cost 25s., for stereographic lens or $\frac{1}{4}$-plate portable camera.—Address, W.E., 2, York-street, Covent-garden, W.C.

I will exchange a 15×13 rolling press, by Knox and Co., of Glasgow, cost £7 10s., for anything useful (lens), or will take £5 10s.; also wanted, a wide-angle Ross's or Dallmeyer's 12×10 symmetrical lens.—Address, W. WESTOBY, St. John-street, Goole.

I will exchange a 6×6 bellows-body camera, with screw to focus and folding tailboard, with carriers for 5×4 and quarter-plates, as good as new, a quarter-plate camera, a good, strong tripod stand, and a 10×8 glass bath, with case and dipper, for a 10×8 or larger Kinnear camera or other good maker, with double slide preferred.—Address, A. F. CLARK, photographer, 18, Glamis-road, Forfar.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

B. H. G.—Twenty grains to the ounce will be quite strong enough for the purpose.

GLASGOW PHOTOGRAPHIC ASSOCIATION.—Paper read at last meeting received.

R. HOLGATE.—Messrs. Nettlefold and Son, High Holborn, will, no doubt, supply all you require.

YORKS.—The apparatus is not an article of commerce. You will be compelled to make it yourself. This you can easily do with a local tinman's aid.

LANCASHIRE LAD.—Send us an example, or be more explicit in describing your difficulties, and we can then, no doubt, assist you in overcoming them.

A BEGINNER.—The "luxograph" or Moule's "photogen" might possibly answer your purpose. The electric light would probably be too expensive.

W. W.—The best plan in practice will be for you to measure the fluids and weigh the solids. This is the general custom when "parts" are given in a formula.

SYNTAX.—The better way to treat the collodion is to use it up for plate-cleaning. If it be as old as you state it will not be worth experimenting with. Better procure fresh.

MAJOR GUBBINS.—The defect arises from an inequality in the coating of the plate with the emulsion, and not from one portion being more sensitive than another, as you appear to surmise.

A. P. SHARP.—There is no such work. If one were compiled it would be quite worthless in practice, as the light is always changing, and no two makers' plate are exactly equal in sensitiveness.

W. G. M.—The enamel picture would have been very good, in all probability, if it had not been over-fired. Next time use much less heat, and do not keep the picture in the muffle for so long a time.

H. SOLTER.—The keeping qualities of the plates can only be tested by actual experiment. We have not kept them longer than six or eight months, but they showed no deterioration during that period.

S. S. S.—There is very little doubt that your failure is caused by employing too strong a solution of the bitumen, although you term it a "dilute one." Bear in mind that the thinnest possible film is sufficient to protect the metal from the action of the etching fluid, which is all that is necessary.

H. G. FOX.—There is nothing new in the fact that certain samples of paper change colour upon prolonged exposure to light. Sometimes it arises from the fibre itself becoming discoloured; at others it is caused by a fugitive pigment added to the pulp to disguise its real colour becoming bleached, and then leaving the fibre the colour it was originally.

A. WARMAN.—Yes; photographs burnt-in on ceramic ware can be produced by making a "carbon tissue" with ceramic colour instead of the ordinary pigments, developing the picture in the ware, and then firing it. The chief difficulty encountered by those who have tried this plan is that, when the heat is applied, the picture is liable to split off before the gelatine is consumed; but it has been accomplished, and some good examples have been exhibited.

G. T. FEARNSIDE.—We have no details as to how the feat was accomplished. However, it may be tried in the following manner:—The camera should be focussed for some distant object in the daytime, and then arranged so that the lens points to the sky. A plate should next be placed in the camera, the shutter drawn, and the lens uncapped. The lightning would then probably impress itself upon the plate. Of course, the experiment can only be made when it is quite dark, as the plate will be exposed all the time.

A. HICKS.—The reason that the gelatine coating does not soften sufficiently to stick to the collodion film is that you have used too much chrome alum in its preparation. Possibly half the quantity would have been sufficient for that particular sample of gelatine.

M. FRASER.—To succeed with the process it is necessary that the plates be prepared with bromide only. If iodide or chloride be present you will not be successful. There are several plans of obtaining reversed negatives, such as stripping the film from the glass, taking the negative with a prism or reversing mirror fitted to the lens, or a reversed negative may be reproduced from the original negative by the powder process. Reversed negatives may also be produced by printing a carbon transparency, and from that making a negative by superposition on a gelatine plate; also by several other methods.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 19th inst., the subject for discussion will be—*On Portraiture in Ordinary Rooms.*

AN AUTOMATIC WASHING TRAY.—Since giving a description in our last issue of the print-washing machine patented by Mr. Hazeldine, of Godstone, we have been offered an opportunity by the inventor of testing its efficacy. Although from the details given anyone possessing a modicum of mechanical knowledge must have known that it would work automatically in the manner claimed, there is always a degree of satisfaction in seeing such action in practical operation. Having placed the tray below a faucet we allowed the water to run in slowly, in the manner shown by the diagram in our last number, and no sooner had it reached a certain height than it rushed over the partition into the previously empty chamber at the end of the tray, which was thus overbalanced and caused to tilt. The syphon then operated and permitted the water to flow out, by which the tray was allowed to regain its former level position, and again to be filled with water up to a certain level, when the tilting and emptying operations were automatically repeated as before. We understand that these trays are to be manufactured in various sizes. They will, doubtless, be found very useful.

PHOTOGRAPHY AND CYCLING.—The second annual photographic lantern social meeting of the Temple Bicycle Club took place on Tuesday evening, the 11th instant, at Anderton's Hotel, Fleet-street, and was a decided success, upwards of 300 of the members and their friends being present. The programme consisted of lantern views, music, songs, and recitations. We will confine ourselves to the lantern pictures, merely mentioning that the music and singing was of the highest excellence. Some two hundred slides were put upon the screen, principally from negatives taken by members of the Temple Bicycle Club, of provincial scenery on their tours, including many well-known bicycling haunts and faces. The applause testified to the pleasure with which they were received, as well as to the skill of the photographers. The slides were specially prepared for the occasion by Mr. J. B. B. Wellington, and were shown by the Sciopticon. A new feature was the way in which the pictures were changed upon the screen, which was generally allowed to be a great improvement. One lantern only was used, and by a mechanical arrangement the picture faded away into darkness, another immediately taking its place—the short interval of darkness being practically imperceptible, and the effect far more pleasing than ordinary dissolving views. The details of the contrivance did not transpire, but we believe it will shortly be brought out by the Sciopticon Company.

LONDON GAZETTE, *Tuesday, March* 11, 1884.

ADJUDICATION.

DUNCAN JOSEPH GRANT, 53, Llewellyn-street, Pentre Ystrodyfodwe, near Pontypridd, artist, picture-frame maker, and photographer.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician,
For the Week ending March 12, 1884.
THESE OBSERVATIONS ARE TAKEN AT 8.30 A.M.

March	Barometer.	Wind.	Dry Bulb.	Wet Bulb.	Max. Solar Rad.	Max. Shade Temp.	Min. Tem.	Remarks.
6	30·26	W	40	38	—	53	36	Foggy.
7	29·99	W	39	38	—	53	36	Foggy.
8	29·85	SW	43	41	—	50	37	Overcast.
10	30·22	W	43	41	—	52	41	Raining.
11	29·25	NE	40	39	—	46	37	Raining.
12	29·69	NW	44	42	—	49	37	Hazy.

JOURNAL OF PHOTOGRAPHY.

No. 1246. Vol. XXXI.—MARCH 21, 1884.

A NEW METHOD OF KEEPING EMULSION.

Continuing from the point at which we left off last week, we have now to consider the most convenient method of storing the emulsion we have already described, assuming, as our experience so far has led us to believe to be the case, that the emulsion itself will retain its qualities for an indefinite period.

As we left it the emulsion has simply been allowed to set into a hard mass in the vessel in which it had been mixed. This is, for obvious reasons, not a very convenient plan if the bulk is to be used up in small quantities. The quantities given last week will suffice for about twenty-four ounces of finished emulsion—more or less according to whether a thick or thin emulsion is preferred—and in its present state it occupies probably between one-fourth and one-fifth of that bulk. It is very undesirable that it should be remelted each time a small quantity is required for use, so that if it be necessary to dilute it by volume it will be needful to store it in separate small bottles (say) of one ounce capacity, each of which will suffice for about five ounces of finished emulsion.

It will readily be understood that in this concentrated form it is quite impossible to squeeze the jelly through canvas or to divide it in any of the usual ways owing to its extremely tough nature. It might probably be cut up by such an arrangement of knife edges as that described by Mr. William Bedford some time ago, and to store it in that form. A certain quantity *by weight* might then be taken and made into a given bulk of emulsion; but in any case, as will be seen later on, it is desirable to have it in a divided form.

Calculating the weight of the ingredients, the bulk should weigh a little over six ounces; or allowing for some slight inevitable loss we may set it down at six ounces. On this computation, then, we may calculate two drachms (or one hundred and twenty grains) by weight for each ounce of finished emulsion. Such proportions we have found in practice to give a smoothly-flowing and, at the same time, quick-setting emulsion.

But a better plan than this exists—the same, indeed, as that recommended some years ago in connection with washed collodion pellicle, only that in this case it is more reliable. This consists in spreading a given quantity of emulsion upon a measured surface of glass, so that each square inch of the pellicle may represent a definite quantity of emulsion. With the quantity given the area represented by a glass plate measuring 8 × 6, or forty-eight square inches, will allow two square inches for each ounce of finished emulsion, and, roughly calculating, the sheet would be about three-sixteenths of an inch in thickness—a convenient thickness for storing and for handling.

A plate of glass of the dimensions named having been edged with strips of paper, so as to form a dish, is levelled accurately by means of screws, and the fluid emulsion poured into it and allowed to set. After an hour or two it will have become so firm that it may readily be dragged or stripped from the glass in a single sheet; but before this is done it will be better to divide it with a silver knife into twenty-four pieces, each measuring 2 × 1, by making three cuts parallel with the short edge of the glass and five the other way. The sections may then be stripped separately, and each will represent one ounce of finished emulsion.

These may be placed together in a suitable jar, or, preferably, wrapped separately in clean paper first to prevent their adhesion if kept. The paper, even if it should become adherent, will be easily got rid of in the subsequent operations. By adopting this plan it matters not how long the emulsion is kept nor how much of the alcohol and water escapes by evaporation, and thus reduce the weight of the flakes; each section will continue to consist of the same proportion of gelatine and silver bromide, and will represent always one ounce of emulsion.

When required for use the desired quantity of the solidified emulsion is placed to soak in cold water. After a few minutes the wrapping paper, if that have been used, may be peeled off and the water changed. It is difficult to fix the proper time during which the pellicle should be allowed to soak, as this will depend upon the temperature, the period it has been kept, and the length of time the coated plates are likely to be retained. It is desirable to remove as much as possible of the contained glycerine, especially if the plates are to be kept long; otherwise the hygroscopic matter might be liable to cause trouble. No difficulty will, however, be experienced in this respect, as the glycerine renders the mass extremely permeable and rapidly diffuses itself throughout the water employed for soaking. Its removal may be judged pretty accurately by the gradual disappearance of the sweet taste in successive changes of water, leaving, in all probability, a slightly bitter taste from the salicylic acid.

The operation of soaking and melting the emulsion will be much quicker than would be the case if the pellicle had been cut to the same dimensions and *dried*, while the fineness of division of the sensitive salts is, we think, better preserved. The soaking will to a great extent remove the alcohol contained in the emulsion originally, though its smell will, in all likelihood, remain, so that in making up the bulk the necessary allowance must be made for an addition of alcohol, if such be desired. After filtration in the usual way the emulsion is ready for use.

As regards the question of whether the sensitiveness changes with keeping, our experience is quite in the negative. If the bromide be allowed to "ripen" during the process of precipitation, or in certain methods afterwards, and it be thoroughly freed from soluble matter, the sensitiveness appears to remain absolutely unchanged after the addition of the gelatine. If the ammonia process be used to obtain sensitiveness the alkali must be thoroughly removed by washing, though the salicylic acid would probably act as a check upon any slight trace that might remain. Any considerable quantity of alkali present, whether accidental or otherwise, is to be avoided, as it tends to induce decomposition resulting in fog. Especially would this danger be present if the glycerine employed were a sample—such as is alleged to be found in the market—made up from or adulterated with glucose. This latter substance in the presence of an alkali is known to reduce the haloids.

On a later occasion we shall probably return to the use of glycerine in other applications in connection with emulsion.*

EXPEDIENTS IN CONNECTION WITH SMALL STUDIOS.

By small studios we here mean those having low roofs. If they possess certain advantages over those of greater dimensions and height, as regards the control of the lighting of the figure, they have also certain disadvantages peculiar to themselves. When circumscribed laterally it is impossible to obtain a group in consequence of the narrowness of the background; whereas, when vertical conditions are considered, in the photographing of a tall man, taken standing, his head almost on a level with the top of the background, the obtaining of a presentable picture under such conditions borders on the impossible. Such are the adverse conditions we now wish to face, and to indicate the means by which they can be successfully overcome.

To have the sides of a background in the same picture with the subjects forming a group, and to have the top of the background with its roller, nails, or fittings vividly and sharply displayed in the immediate vicinity of the head of the tall, martial-looking figure, whose "counterfeit presentment" is being prepared for the admiring gaze of future generations, are necessities, or have been considered as such. Happily this drawback is not without its remedy.

The remedy to be here described, and which is not new even in this special application, is one based upon the principle involved in a system of vignetting introduced in the earliest days of the art. It may not be known to the majority of those photographers who have devoted themselves to the practice of the art-science within the comparatively brief period of a quarter of a century, or whose acquaintance with its history does not greatly antedate that period, that the earliest method of producing a vignette portrait consisted in interposing between the sitter and the camera a large white or light-coloured disc, in which there was an aperture having a serrated margin, through which the lens peeped at the sitter, or so much of him as could be seen through the aperture. Gentle rotation during the time of exposure ensured the serrated edges not being seen, and the result was a daguerreotype having a figure beautifully vignetted into a white ground.

This is the principle involved in the manner of extending the apparent dimensions of a background either at its sides or its head which we shall now describe. Let us suppose, therefore, that the head of the figure is so near the top of the background as to ensure both being seen in close proximity, and thus to entirely destroy the artistic effect: how is this to be obviated?

At any point between the camera and the sitter, but by preference much nearer the former than the latter, let there be interposed a screen depending from a line stretched across the studio. This screen must harmonise in colour with the background, and hang so low as only to cut off the view of the top of the background from the camera lens. The screen will thus be vignetted into the background; for being so close to the lens its lower edge will be quite out of focus. It thus forms a visually-continuous sheet with the background, and extends as far overhead as the photographer desires. It is, of course, necessary that the colour of the background and of the interposed screen be alike; otherwise there will be a want of uniformity in the tint apparent.

Desirous of seeing to what extent this joining-on of a top piece to a regular background could be carried, we carefully erected a background composed of a uniformly-even web of cloth, and at a height of twelve inches above the sitter's head we placed a black cross-bar which extended from side to side of the field of view. About forty inches in front of the camera a sheet of tinted cardboard, harmonising in colour with the background and of about two feet by eighteen inches in demensions, was suspended by the two upper corners, the "dip" being just so low as on the one hand not to interfere with the head of the sitter, while on the other hand it cut off entirely the cross-bar, which for the sake of the experiment we had meant to be very obnoxious. The degree of adjustment necessary to effect the perfect reconciliation of the main background with its subsidiary was but trivial, and when an exposure was made and the negative developed it was absolutely impossible to discover that any unusual expedient or trick had been resorted to in order to obtain the effect which was secured. In this picture there is a large space over the head of the figure—so large indeed as to lead to the belief that the background was one possessing exceptional height. What we have said will, without entering into further details, indicate the means by which the evils of a low background can be obviated.

In a similar manner may the too greatly circumscribed sides of a studio be made to give way to an apparently open lateral expanse. What is absolutely necessary in the carrying out of this idea in a perfect manner is to see that the small interposed sheet is of such a colour as to harmonise with that of the real background behind the sitter.

The idea here elaborated is one of great excellence. We are unaware by whom it was first mooted, although we have a hazy recollection of meeting with it many years ago. We know, however, from having conversed with some of our more intelligent readers that it is new to them, and, therefore, we publish it for the benefit of all who, from having low studios or the latter being otherwise unfavourably situated, are in a position to profit by the idea to which we have drawn attention.

ON THE RESTORATION OF FADED PHOTOGRAPHS.

Although a considerable amount of attention has of late been devoted to the subject of the fading of silver prints and its causes, very little practical good, we fear, has resulted therefrom. It is true the different discussions which have taken place have elicited the fact—or, rather, brought it into more prominent notice—that prints made from vigorous or dense negatives on a highly-sensitised paper are, all things being equal, those which possess the greatest degree of permanence it is possible to obtain with silver printing.

Unfortunately at present thin negatives and lightly-sensitised paper are the order of the day, and there is apparently but little chance of their being departed from; so that, notwithstanding all that has been said and written, we surmise things will go on pretty much as heretofore. Therefore there is little hope that the photographs of the immediate future will prove any more permanent than those of the past. Now, seeing that there is so little chance of any material improvement being made in the direction of securing greater permanence, it is somewhat a matter of surprise that so little attention has hitherto been paid to the subject of the restoration of those pictures which have faded, or of arresting the decay in others when it first makes its appearance. Up to the present time there is unfortunately no satisfactory method known for accomplishing this with paper photographs.

With daguerreotypes the case is different, for they can be successfully restored. But daguerreotypes do not fade in the sense that silver prints do. The image itself does not fade away; it is only the silvered surface of the plate that becomes tarnished, and it is simply the tarnish which obliterates the image. If this be removed the picture is at once restored to its original—or very nearly its original — condition. This is easily accomplished by treating the plate with a solution of cyanide of potassium—ten to fifteen grains to the ounce—which dissolves off the tarnish. When the whole of this is removed the image appears as good as ever. After the tarnish has been removed it is necessary that the plate be well washed (finally with distilled water) and dried. It is then fitted, air-tight, in its frame or case, so that it is thoroughly protected from the action of the atmosphere. If so protected it will remain unchanged. If, however, at any future time by the action of the atmosphere it should again become tarnished it can be restored once more by the same method of treatment.

But to return to the subject of paper prints. It has been surmised by some that when a paper print shows the first symptoms of fading—upon the supposition that it must contain hyposulphite of soda—the fading may be arrested, or at least checked, by re-washing

* In the thirty-sixth line of the second column of our article last week, for "glycium" *read* "glycerine."—Eds.

it; but many who have tried the experiment have not found this to be the case. On the contrary, in several instances the fading has been hastened by this treatment. In any case, very little advantage is gained by re-washing.

What becomes of the photographic image when the picture fades? It is a well-known axiom in chemistry that nothing can be destroyed. It can only be made to take a different form or condition, consequently the image (or what composed it) must still exist in the paper in some form or other; for we have no reason to assume that it has become volatile and evaporated. Hardwich says it is converted into sulphide of silver, and this, although dark in colour when in mass, is of a pale yellow when in an attenuated layer. Now, if the silver and gold which once composed the picture be still existent in the paper, it might fairly be assumed that modern chemistry could devise some means by which the latent image might be developed or restored to its original condition. Many ways of doing this have at times suggested themselves to experimentalists, but, up to the present, with no practical result. There is no question that, if a method can be devised by which faded paper prints may be restored to their pristine condition, it must prove invaluable. Here is a wide field open to experimentalists wishing to acquire fame, and to such we commend the subject for consideration.

Although at the present time there is no known means of actually restoring the image when once it has disappeared, yet there is a method by which faded paper prints may often be very much improved if not actually restored. In our article on *Old Prints* in our last number we mentioned that if the strong yellow tint in some of the very old photographs shown at the South London Photographic Society's last meeting were removed a bold, vigorous picture would remain. Now, this is precisely what is accomplished by the method to be described. It may here be mentioned that the plan was first published by Mr. R. F. Barnes nearly thirty years ago.

The treatment is simple. It is only to immerse the yellowed print in a dilute solution of bichloride of mercury until all the yellowness disappears. It is then well washed in water to remove the mercurial salt. If the print be a mounted one it is by no means necessary to unmount it previously to treatment. All that is required in this case is to keep it in intimate contact for a time with blotting-paper charged with the bichloride; indeed, this is the plan originally suggested by Mr. Barnes. By the bichloride treatment no lost detail is actually restored as some have imagined. It is simply that the sickly yellow colour which, as it were, buried the delicate half-tints, or what remains of them, is removed, and thus renders the picture bright and clear. Pictures which have been treated with the mercury always possess a much warmer tone than they did originally, as the purple or black tones give way to a reddish-brown or reddish-purple—more or less bright according, probably, as gold or sulphur had been the principle toning agent.

Here a question very naturally arises with regard to the future permanence of pictures which have been thus "restored," seeing that negatives intensified with mercury or transparencies toned with it are so prone to change. In answer to this we may mention that they appear to be permanent—at least that is our experience with some that have been done for many years. There appears to be no further loss of detail, and the whites retain their purity. Indeed, since undergoing the treatment with mercury no alteration is yet perceptible.

MECHANICAL METHODS OF TINTING PHOTOGRAPHS.

The interesting communication by Mr. Kurtz, described in our *Transatlantic Jottings*, will naturally recal to the mind of many an old practitioner the numerous methods of "improving," tinting, background-making, and the multitude of other mechanical devices which from time to time have been practised by the profession, or as specific nostrums brought before their notice. There would not seem, *a priori*, to be much connection between fire-irons and the production of pictures; yet, last century, a most fashionable style of picture was the "poker picture," which was produced by charring or singeing the surface of white wood by the aid of a red-hot poker. By charring to different degrees of intensity, the various depths of tones represented in a bistre drawing were thus imitated, at the hands of an expert, with pictures of considerable merit. Now we have Mr. Kurtz taking a photograph by means of a closed box and a pair of bellows distributing a cloud of fine colour, which falls over the surface of paper so as to tint it in a delicate and even manner. Many years ago a somewhat similar effect was obtained by sifting fine colour through a large muslin sieve, and by vigorous agitation causing the colour to descend almost as a cloud upon the picture placed at the bottom of a box. We are unaware if ever this method found its way into print, but it was communicated to us many years ago by an expert—a gentleman of great artistic skill—whose coloured photographs are among the very best pictures of the class we have seen.

This particular mode of manipulating pictures—the laying on of an even tint—is practised in an immense variety of forms by many clever artists as well as by the more mechanical stipplers who aim at nothing but "finish," and to whom monotony and smoothness are the limits of perfection. A well-known—we might say a notorious—process of this kind was devised a number of years ago, and was brought before photographers in such a dexterous manner that many thousands of pounds must have been netted by the inventors. The method of advertising and pushing the process was a marvel of commercial dexterity; so successful was it that some of the best business men in the profession were drawn in. Naturally, the carefully-cultivated *furore* soon died, and concessions for the patent rights — which at one time were valued at hundreds of pounds for a district—soon went begging for a five-pound note. We think it by no means undesirable at times to bring before our readers a reminder of past follies of this description, and for the younger generation of photographers, who may not have come into contact with anything of the kind, our remarks may serve as a word in season, for there will always be process-mongers.

We have in our mind as we write the doings of a singularly-facile and clever worker with powder colour, with whom we once came in contact a number of years ago. He must, we should think, be no longer alive, for the mode of operations he adopted and the methods of his art were well adapted to trap the unwary photographer anxious to learn a "wrinkle" or execute artistic work quickly and cheaply. This man formerly travelled through the country selling his boxes of materials and giving lessons in the working of them, and when once he succeeded in securing the ear of anyone to whom he had gained access, he was able in a very short period to execute marvellously-effective pictures in a space of time so brief as to be almost incredible. His sole apparatus, so far as our recollection carries us, was a box containing a black powder (very like the well-known "stumping sauce" of the worker in crayons), a piece of black chalk, a few stumps, and a large woolly bos more like a powder-puff than anything else. With a few dexterous sweeps of this puff, first filled with a quantity of the powder, he coated a good-sized piece of paper in a second or two, giving it greater depth in some places than others. A pocket hankerchief swirled round here and there removed the stain, and soon clouds were produced; a few black touches gave tree trunks, and the foliage was indicated equally quickly by a few touches with the thumb. A sweep or two of the handkerchief gave an eddying stream, and rocks were indicated with equal facility and rapidity. The final touch was given by a sweep, we believe, of the coat-cuff, which created a foaming cataract dashing among the rocks! In as brief a time almost as we take to write it this clever fellow produced a really effective picture, with apologies for its necessary incompleteness, owing to the short time occupied in its production. "More finish, of course, could be produced by giving more time to it." The price of a box of materials, with a lesson to explain complete details, was only two guineas! We do not take any very great merit to ourselves for not investing the two guineas; but if we have made clear to our readers that the merits of the picture so obtained were due, not to the process but to its expositor, our end will be obtained.

The laying on of a tint, and then removing portions of it to obtain effect, is a perfectly legitimate "dodge," and much time can be saved by it. A life-size head stumped over in grey with a large stump, and then the broad lights removed by a piece of bread and the finer points by a piece of the crumb worked to a point, can be effectually modelled in a much shorter time than if all this tone had to be hatched or rubbed in with a small tool. The darker portions can be equally well executed whether there be any tint already upon them or not.

In a similar way, some would say not legitimately, coloured crayon heads are started by giving a wash of flesh colour in water-colour, and then, after it is quite dry, putting on the local and other colours with either stumps or point of pastil. Such methods may be decried by some as false pretences, passing off as crayon what is not so; we merely offer the plan for what it is worth, and do not give it any name. But it must be said that some of the great painters whose works have posts of honour in our national collection are well known to have favoured such modes, and there are now to be seen oil-colour paintings which have a strong body of water-colour laid on before the oil.

We are glad to see that a method of tinting faces on a small and cheap scale, as once devised for use with aniline colours, seems to have entirely gone out of existence; yet, with a selection of colours that would not fade, effects—not artistic, certainly—could be quickly and cheaply obtained. These colours were weak, spirituous solutions, and were first put in drops out of the brush upon the face. Quickly spreading they gave an even tint to all the paler parts of the print, but had no power to give a visible stain to the darker portions. A minute point of slightly darker colour applied to the cheeks spread sufficiently to give a softened outline to the spot, and so avoided all need for stippling. We name this method now more to warn our readers not to make use of it if, as we thought seemed probable some little time ago, it should be brought forward again. If it were re-introduced, and upon so fugitive a groundwork further painting of a legitimate kind were added, the result, though cheaply obtained, would be so evanescent as to increase still further the evil reputation that "coloured photographs" have so long suffered under.

We think we have now said sufficient to show that mechanical aids to the tinting of photographs may, when in suitable hands, be capable of aiding in the production of good results; but when appeal is made for the adoption of, and the paying for, a process on account of its intrinsic value for obtaining artistic results quickly and by untrained fingers, we would at once say—beware! Artistic effects are the result of education and practice in art and art methods, and we cannot conclude better than by endeavouring to impress upon all who would invest in "processes" that there can be no fine art by machinery.

In the report of the Edinburgh Photographic Society we notice the mention of a new adhesive substance termed "gloy," and amongst its possible applications the mounting of prints is suggested. For this purpose it is, however, eminently unsuited, as our readers will understand when we inform them that it is made, we believe, by treating rice flour with caustic alkali, the latter being afterwards more or less carefully neutralised by means of some cheap acid. It is, of course, within the bounds of scientific possibility to deprive the product (by dialysis or other means) of its deleterious ingredients; but we question whether this would pay commercially, or whether the balance of its advantages as a mountant would justify the extra cost As an adhesive for ordinary purposes we can speak of "gloy" very highly.

The curious phenomenon mentioned in the postscript of Mr. H. Y. E. Cotesworth's communication in another column may be observed by any of our readers who will take the trouble to make a rather weak solution of chrome alum. In this state, or in a thin layer, the chrome alum solution has a green colour by daylight, but, as the strength or the volume increases, the tint changes to purple. If the green solution be examined by gaslight its colour will be found to change to a clear violet-purple, as described by Mr. Cotesworth. A solution of chrome alum made with hot water exhibits the green colour under all circumstances, both of light and concentration, but after some time gradually reverts to the red condition.

The current number of the *Athenæum* is interesting photographically in many directions. There is a review of Dr. Eder's *Chemical Effect of the Spectrum*, in which the writer speaks most strongly of the absence of acknowledgment of the value of the services of noted English workers, though a very sufficient reference is made to continental experimentalists.

It contains also a review of Vol. II. of the autotype reproductions of the *Liber Studiorum*, which it states is, on the whole, superior to the first volume—a statement involving great praise, as it reviewed in a very favourable manner the plates of the first volume. Speaking of the Frontispiece, it characterises it as being first-rate, saying that it could hardly be better given than by this reproduction, which shows the delicacy of the renowned mist-laden veil of light to perfection. Altogether better evidence could not be offered of the value of the process for the reproduction of works of art.

At the meeting of the British Association it appears that Professor W. G. Adams will give a lecture instead of Mr. W. Crookes. The trip need be by no means an expensive one, for we learn that the sum of fourteen thousand dollars has been allotted for the reduction of fares of members, in addition to the liberal allowance made by the steamship and railway companies. All the American railways will reduce their fares one-half. Only those persons, however, who were elected at or before the Southampton meeting are entitled to share in the fourteen-thousand dollars' subsidy.

Of late years several experimentalists have investigated the action of various portions of the spectrum upon the growth of vegetables, and in the March part of the *Transactions of the Chemical Society* there is an appendix to a paper by Mr. A. B. Griffiths detailing "the influence of certain rays of the spectrum in the growth of plants growing in an iron manure." It is a singular fact that the use of iron developed considerably increased growth irrespective of the treatment with special rays, and with regard to the latter he found that the more photographically-actinic the character of the light employed the less the quantity of iron absorbed. Thus, in the violet portion of the spectrum only so much iron was taken up by the plant as gave ·15 per cent. ferric oxide in the residue, while in the yellow 2·51 was taken up.

The danger of water taking up lead under certain contingencies, when stored in a lead cistern, has long since been discovered, and lately attention has been called to the ease with which zinc may be dissolved by water standing in vessels made of that metal, or running through pipes of iron coated with it—"galvanised iron," as it is termed. As many cisterns are so made it will be well for those of our readers who employ them to make a note of this fact, as, though the presence of zinc does not necessarily indicate injurious action in photographic operations, it is desirable to know whether water is or is not contaminated with other than the usual salts. Mr. Thomas Stevenson, M.D., in an old number of *Guy's Hospital Reports*, states, referring to this question, that "zinc in solution in potable waters is best detected by the addition of potassic ferrocyanide to the clear water after acidulation with hydrochloric acid, when a whitish cloud will immediately form if zinc be present. Of course this reaction must be confirmed by other tests. I know of no test for zinc which is so delicate as this."

In reference to the photographing of microscopic objects, it should be known that the results are governed, to a greater extent than might be thought possible, by the mode in which the object has been prepared. Mr. Lewis Wright, in writing to the *English Mechanic*, points out that a well-known microscopic preparation maker informs him that the demand for slides is for an average quantity at an average price, and that any demand for photographic purposes is quite recent. Such slides, can, however, be prepared readily as special objects; of course, the price will be in accordance. Our readers may look upon this as a decided "wrinkle," if they wish to produce photomicrographs of the highest quality.

CHEMICALLY-PREPARED DARK ROOM WINDOWS.

Just at present green as a colour for the light of the developing room appears to be in considerable favour; but in many cases a difficulty is experienced in procuring either glass or paper of the desired tint. The so-called "cathedral green" glass is not known by the merchants and dealers, for the sufficient reason, as it now seems, that there is no such thing; and "green tissue paper" is a rather elastic definition. Those, therefore, who have not the opportunity of actual inspection of the proper tints, as recommended by Mr. W. E. Debenham and others, are placed rather at a disadvantage.

I have been experimenting for some months past in the direction of producing (preferably by chemical means) a coloured medium or media of different colours which shall be suitable for the purpose, and the preparation of which may be described in definite terms so as to be capable of repetition at will, and with an identical result, by any person who may so desire. This is, perhaps, not attainable in its strictest sense ; for, though a chemical formula may be stated with sufficient exactitude to enable the colouring matter itself to be produced with practical uniformity, I fear that the medium on which it is spread, or throughout which it is diffused, will always present some features leading to uncertainty. This must, at least, be the case, where paper, textile fabrics, gelatine or other films are concerned ; but, if a layer of a given thickness of a solution prepared by a definite formula be used in a glass trough of suitable construction, it seems to me that a near approach to exactitude and uniformity will be secured.

Though I should have preferred for convenience sake one of the former plans—especially a coloured gelatine film or films—I have not yet succeeded to my satisfaction in securing the desired results, and have, therefore, confined myself, so far, chiefly to the use of coloured solutions contained in water-tight troughs of simple construction. The troughs I have used consist of a plain frame of wood of the section shown in the diagram, *fig.* 1 being a single trough, and *fig.* 2 a double one for two solutions of different colours.

FIG. 1.

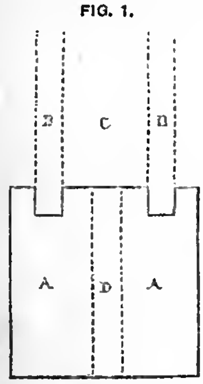

FIG. 2.

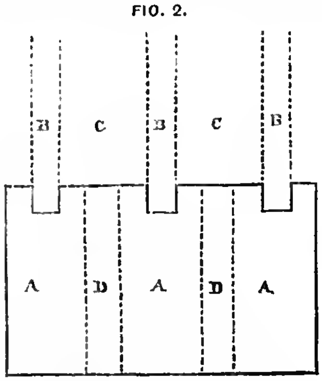

A A is the wooden framework in section, B B glass plates cemented into the grooves by means of shellac or marine glue, and C C the space between the glass plates to be filled with solution. D D are apertures pierced through one side of the wooden frame by which to introduce the solution. The woodwork, before being put together, is rendered waterproof by means of any suitable varnish, and the filling apertures are closed by means of small wooden plugs. I have, as will be seen, adopted half-an-inch as the thickness of the layer of solution; but if this be considered to render the frame too bulky it may be reduced to a-quarter of an inch, and more concentrated solutions employed.

As regards the solutions employed: I have confined myself to two or three as being the only suitable ones I have yet found—that is, which are stable and do not deposit their colouring matter. Many of the mixtures with which I experimented in connection with paper and films I found wholly useless for this purpose, and so I entirely discarded them.

For yellow or orange colour I find nothing better, in a general way, than potassium bichromate in strong acid solution if a full orange be desired, and neutralised by means of an alkali for paler yellow. Solution of chromic acid, which gives a much deeper red, I have not ventured upon using, in consequence of its probable action on the wood frames. For green colours I have used two chromium compounds which are easily prepared, and which between them and with certain modifications, give a wide range of greens—all having much of the character of what I suppose the so-called "cathedral" to be, namely, varying through olive of different shades of yellowness to the well-known chrome green. These substances are chromium sulphate and chromic oxide, both of which are very easily prepared from the commercial chromic acid.

The first is a very soluble and uncrystallisable salt of a beautiful green colour, and, therefore, lends itself readily to the formation of a solution of great depth of tint and with little tendency to form any deposit. It is prepared by reducing a strong solution of chromic acid by means of sulphurous acid. Thus, if the latter, in the form obtained commercially, be added gradually to a strong solution of the former the deep red colour disappears, and after passing through various tints of brown and yellowish olive-green it finally changes to a full green of great beauty, which may be diluted to any desired tint. The chromic acid is deprived of a portion of its oxygen, being reduced to chromic oxide. The oxygen converts the sulphurous acid to sulphuric acid, which, in turn, dissolves the chromic oxide, forming chromium sulphate, thus:—

$$2\,Cr\,O_3 + 3\,H_2\,SO_3 = Cr_2\,(SO_4)^3 + 3\,H_2\,O.$$

A still better plan for those who are accustomed to chemical manipulations is to pass sulphurous anhydride or sulphurous acid gas through a concentrated solution of chromic acid to saturation. This will give a solution of deeper colour, but without proper chemical appliances the operation is not a pleasant one.

Those who are unable to obtain chromic acid may prepare it as follows :—To a hot, saturated solution of potassium bichromate add cautiously, in a thin stream, stirring all the while, about twice its volume of strong sulphuric acid. Care must be taken not to add the acid too suddenly, or violent "spirting" of the highly-corrosive liquid will result. On cooling, crystals of chromic acid will separate. These are freed from the mother liquor and drained on a porous tile or over a plug of "glass-wool" in a funnel. On no account must filter paper or any organic substance be used, in consequence of the powerful oxidising action of the chromic acid. The drained crystals are then redissolved in a very small quantity of boiling water and again treated with strong sulphuric acid, which will precipitate the chromic acid in the anhydrous state, leaving nearly the whole of the potassium sulphate behind in the two mother liquors.

This preparation is quite pure enough for our purpose, though, I may here remark, it is not desirable to have any but the slightest traces of potassium sulphate remaining. Otherwise, upon reduction of the chromic anhydride with sulphurous acid a double salt of chromium and potassium (potash chrome alum) will be formed, which, though, perhaps, green at first, soon assumes the well-known violet tint of many of the chromium compounds. This, it is needless to say, is scarcely a suitable colour for a dark-room window.

It is for this reason that I prefer to use separate solutions of different colour rather than modify the character of the green solution by mixing with it the yellow bichromate. It is true that a very great range of tints may be obtained in this manner, but their permanency is not assured.

Another solution which I have spoken of as being prepared from chromic oxide consists in reducing the acid mixture obtained by the action of sulphuric acid upon potassium bichromate with sugar. If, when the hot mixture has somewhat cooled down, it be diluted to prevent crystallisation, and a lump of sugar be added, it will rapidly acquire a rich, deep green tint. The primary cause of this change of colour is, no doubt, the formation of chromic oxide, probably held in solution by excess of sulphuric acid or in the form of a double salt. Theoretically, this mixture is to be avoided for the reasons I have given above ; but, practically, I find that a quantity I have had preserved in bottles and test tubes for some time does not seem to have changed colour.

I have already said that I have so far not succeeded satisfactorily in applying these green solutions to paper or gelatine films ; but my efforts in that direction were not persevered in to any extent. The difficulty I met with was in obtaining a colouration of sufficient depth, and in the deliquescence of the substances and consequent stickiness of the papers and films when extremely-concentrated solutions were employed. If a deposit of chromic hydrate can be obtained in the body of a thin, even paper, I think that in combination with another paper prepared with plumbic chromate we might easily secure all the advantages claimed for the combination of canary medium and cathedral green glass.

H. Y. E. COTESWORTH.

P.S.—Since the above was written I have made a curious observation. Several of the examples of mixed solutions—that is, those which contain potassium as well as chromium, whether as sulphate of potassium or as chromate—while appearing to the eye perfectly green *by daylight* present the well-known purplish-violet colour *by gaslight*. On first noticing this violet colour I supposed that the solution had changed suddenly. It was only by going repeatedly from daylight into the dark room, and *vice versâ*, I could convince myself that the solutions while presenting this curious instance of dichroism remained still unchanged. What appears even more curious is that, when examined by means of a simple prism—not a spectroscope—in daylight only green rays (the visual colour) are transmitted, while by gaslight the transmitted colour is violet. I send you a bottle of this dichroic solution.—H. Y. E. C.

POLARISED LIGHT AND PHOTOGRAPHY.

As you are discussing the subject of polarised light, allow me to suggest a line of inquiry and experiment which has not been touched upon, but which, I believe, would be found both fruitful and interesting, and is more intimately connected with photography itself than any of those named.

The modern theorics of chemistry tend more and more to relate chemical reactions to the *dynamical* relations of the atoms and molecules of matter. Taking the most popular and photographic example as an illustration, it is held, for instance, that (roughly speaking) the chemical combinations employed by the photographer are almost literally *shaken* apart and into new combinations through the vibrations communicated to them by the luminiferous ether. It is very easy to understand such a theory generally, and also to see how vibrations of any given period may affect atoms of different substances very differently, since the periods of these latter, being of different weights, would probably differ in some way. We can even see how and why the quickest or violet vibrations should be on the average most effective—just as a piece of wrought iron is comparatively unaffected by slow movements, but by quicker vibrations is soon converted into a crystalline state. One of the great outstanding difficulties of the theory has lately been partially removed by the supposition, just referred to by Captain Abney, that the vibration-periods of atoms may possibly vary at different times.

But what has all this to do with polarised light? Well, it *may* have a great deal. In the ordinary light of the photographer, while the vibrations of the ether as they reach his plate are *parallel to its surface,* they take place in all azimuths or angles with the horizon. But supposing the same image cast by plane-polarised light: *all the v brations are in one parallel direction*, and it can hardly be that this great difference shall have no effect upon the dynamical result of these vibrations. Again: in circularly-polarised light we have absolutely circular vibrations. It is in the absolutely *definite paths* of the disturbances set going on the surface of the plate, instead of a mixture of all paths, that (upon the mechanical or dynamical theory) we ought to find, somehow or somewhere, marked differences of behaviour. Whether or not such differences can be traced, and if so when and how, seems to me a matter which, at the present stage of knowledge, urgently demands investigation.

Let me only remark, in conclusion, that a complete "polarising apparatus" ought not to be employed. We do not want (in this line of experiment) to photograph or investigate polariscope "effects" in colour or light and shade; that is done every day. For plane-polarised light, we only need light which has passed through a *polarising Nicol only*, and whose image "shows" no more structure than a common image. If circular vibrations are investigated, then we should want one Nicol and a quarter-undulation plate—no more. The image would be only half as bright; but it is quite a possible thing that these disturbances of *uniform and fixed direction* might be more energetic in effect upon at least some substances. As I fear the matter will be, for some time at least, outside my own possible field of experiment, I desire to recommend it to such as can follow it up amongst your readers.

LEWIS WRIGHT.

STANNOTYPE.
No. VII.

In principle the development of the gelatine relief is identical with that of a carbon print on glass, but the extra thickness of the gelatine film brings about certain practical differences; while, probably, the greater length of time occupied in drying after sensitising the relief tissue, by decreasing its solubility, aids in prolonging the duration of the development. We have, indeed, not only a greater thickness of gelatine to work upon—a greater quantity to dissolve and a greater depth to reach—but we find it also in a less easily soluble state. If it be added that the greater thickness of the relief tissue renders it far more liable to curl up and leave its glass support—a trouble that ordinary carbon printers will sufficiently appreciate—it will be needless to point further to the necessity for greater care in every department of the development. Let us now take the exposed tissue as it comes from the printing-frame.

The first matter for consideration is the glass support. This, like everything else in connection with Woodburytype or stannotype printing, must be of perfectly even surface. Plate glass is absolutely necessary, as any inequality in the surface must inevitably produce its result in the print. From one-eighth to three-sixteenths of an inch will be found a suitable thickness, though this is not a matter of consequence. Thinner glass may be employed if desired, as all the surfaces, both of glass and press, being perfectly flat and no great degree of pressure necessary, there is little risk of fracture.

Next, as to the preparation of the plate before transferring the exposed tissue: it must, of course, be perfectly clean and, before further treatment, carefully dusted. The next operation is to apply a substratum, as to develope successfully on the bare glass is a practical impossibility. Many operators content themselves with a simple collodion substratum, such as is used in developing carbon transparencies; but the increased care which this necessitates when employing the thick relief tissue, renders it a less desirable means than the alternative method with insoluble gelatine as the basis.

We therefore recommend a substratum consisting of a five- or six-grain solution of gelatine, very carefully filtered, and to which is added, just before applying to the plates, a quarter of a grain of chrome alum to each ounce. The precautions necessary in making this addition are sufficiently familiar to all who have used chrome alum in connection with gelatine; but, for the benefit of those who have not had that experience, it should be pointed out that if added in strong solution the chrome alum will precipitate a portion of the gelatine and fail to mix properly. To obviate this it is desirable to make the gelatine solution in a more concentrated form than is required for use, reserving a considerable proportion of the water for the solution of the chrome alum, and both solutions having been carefully filtered are mixed at a tolerably high temperature, very thoroughly stirred, and again passed through two or three thicknesses of muslin to remove air-bubbles. The complete solution must be kept liquid the whole time until used, as if it once solidifies it cannot be again satisfactorily liquefied.

A number of plates may be coated with the substratum, dried, and kept ready for use. The glass having been well cleaned and dusted is coated with the warm gelatine solution as with collodion, the surplus being drained off in the same manner. Should any difficulty be experienced in its flowing, from five to ten per cent. of alcohol may be added. The plates are then reared on end in a cupboard or rack in a place free from dust and allowed to dry.

The tissue being ready for development is immersed in water to soften. While this operation is proceeding the surface should be carefully rubbed with a pledget of cotton wool or a small pad of thoroughly-wetted wash-leather, to remove any dust or other particles which may have adhered to it. It is allowed to become thoroughly limp, and is then placed in contact with one of the gelatinised plates—which has also been soaked in water for a few minutes—and the two are brought into intimate contact by means of the squeegee. Both are then placed under pressure for at least a-quarter of an hour—preferably for double that time—when the development proper may be proceeded with.

The portion of the manipulations just described differs only from the ordinary practice in carbon printing in the necessity for greater care, arising from the increased thickness of the gelatine film. A longer soaking of the latter, more careful squeegeeing, and an increase of the time during which the surfaces remain under pressure before development will, if attended to, secure all that is needful.

The plate carrying the tissue is first placed in a flat dish containing water the temperature of which is at first not higher than 100° Fahr., which may be increased until it reaches 120°. This part of the proceedings must on no account be hurried. As soon as the paper backing shows an inclination to loosen the attempt may be made to detach it; but no force should be exerted, otherwise the whole film will, in all likelihood, become detached from the glass. Nor must the temperature of the water be increased beyond that mentioned; indeed, it is preferable, if possible, to keep it five degrees lower. The golden rule in the development of the relief is "patience" and, it might be added, "coolness." A somewhat refractory film, at first, will yield to prolonged soaking without any increase of temperature or the exertion of force, and eventually the paper will strip off with perfect ease.

The gelatine surface having been laid bare it is allowed to remain for a minute or two in the same dish; the plate is then transferred to another vessel kept specially for development, consisting of a zinc tank fitted with grooves, into which the plates slide as into a plate-box. Here it may have to remain for some hours according to the nature of the subject, the depth of the relief required, the exposure, as well as the age of the tissue, all of which circumstances affect the rapidity of development.

During this period it is, of course, necessary to retain the temperature of the bath at or about the point that has been named; and, as it is obviously inconvenient, if not impossible, to give continual personal attention, some expedient by which the temperature may be automatically regulated is desirable. Several forms of thermostat suitable for this purpose have been devised; but as it is intended shortly to devote a special article to this subject, we refrain from entering into the matter here.

TRANSATLANTIC JOTTINGS.

In taking up the *Photographic Times* (New York) we have to look a second time at the title to be certain we do not make a mistake; for we are so accustomed to the old, quiet, but effective back—more like a piece of bronzed albumenised paper than anything else—that the new and gayer cover (mostly like nothing in particular) causes us to think for a moment that we have taken up the wrong publication. A glance at the contents, however, assures us that we have made no error, and we are content to jot down our extracts of current matters photographic across the water.

Mr. Jabez Hughes lately gave before the Photographic Society of Great Britain a very interesting *résumé* of photographic progress during the last thirty years, and Mr. Bogardus, early last month, gave an account of his personal experience, extending over a long period, in a paper entitled *Thirty-Seven Years Behind a Camera.* We cannot, of course, repeat it in full, but a few extracts will give our readers some idea of its scope and style. He narrates that he started photographic operations in 1846, and only paid fifty dollars for outfit and instructions, and this at a time when exposures ranged about four minutes. Photographs and natural colour process-mongers were rife at that early period, and Mr. Bogardus gives an interesting account of the unmasking of an early member of that fraternity. "Cheap Jack" photographs existed at that embryonic period of commercial photography, and an account is given of a twenty-five cent studio where immense numbers were taken, and where, if a sitter were dissatisfied, he was told to pay and try again! One of Mr. Bogardus's pupils, who had attended to have further lessons as he was in a difficulty, asked him, after watching his operations some time, if he "focussed afresh every time," evidently considering it sufficient to perform the operation once a day. He gives an interesting recollection, recalling the old never-to-wink instructions—"Stop it! stop it!" exclaimed an old lady; "I winked." "A little thing, though full-length—a man standing by a fluted column," gives as good an idea as possible of the old original *carte-de-visite* as it first appeared. We cannot conclude this brief abstract better than by repeating his advice—"strive to excel rather than undersell."

At the same meeting Mr. Kurtz gave some valuable hints upon the production of crayon pictures, and described a most ingenious method he had devised for quickly covering the surface of paper to avoid labour in working up by the point of the crayon. To "kill the large white surface of paper he had experimented with all kinds of things, such as coffee, tea, &c., and then he happened to think of a very nice smoke-after-dinner picture made in artistic circles in Europe." Mr. Kurtz filled a tumbler with smoke from a cigarette, inverted it over a piece of paper, and showed how it became tinted. He stated that, following this idea, he had filled a large box with smoke, and, putting the paper in, obtained a fine yellow tint: it smelled too strongly of tobacco to be of any use. Finally, he constructed a special box, into which, by means of a pipe attached to a pair of bellows, he blew a fine cloud of powder colour, and then introduced the crayon paper, which was withdrawn, after a few seconds, tinted evenly any colour according to the pigment employed. He then showed how, with the tint as a groundwork, the lights or, indeed, complete objects could be completely stopped out by laying screens on the paper during the tinting. Mr. Kurtz further demonstrated how a photograph could be tinted in colours, and then the background put in by the apparatus described. He explained how lights could be put in the flat tint by taking off the pigment with bread. The whole lecture, it will be seen, was full of hints of great value, and, when illustrated by the lecturer's experiments, must have conveyed instruction in a very full and novel manner.

Mr. Clemons—whose name in connection with silver printing is very familiar—narrates an experience which, we must say, is to us as surprising as novel. Having taken into stock a new sample of albumenised paper and put into use with his usual solutions, he "was surprised to find how mushy and soft the albumen had become." He went back to his old brand, and that also worked "mushy and soft." After sundry experiments he hit upon a cure. He placed all his prints in a bowl of hot water before toning, and the evil passed away! The remedy seemed as singular as the disease.

The chairman of the meeting at which Messrs. Kurtz and Bogardus's papers were read gave his experience with iodide in the pyro. developer. It may be remembered that it was the same experimentalist who gave the mercury-iodide process, which has not succeeded in the hands of those who have tried it in this country. He stated a number of facts novel in chemical lore. Thus, iodide of lithium formed an insoluble iodide, especially in hyposulphite of soda, and it took at least an hour to dissolve the iodide. He gave "a formula by which the colouring matter of the pyrogallic acid which dyed the gelatine film yellow would be prevented from doing so. He destroyed the yellow and the property to dye the film by using ammonio-citrate of iron."

In the *Photographic Times* (New York) we find an excellent article on telescopes for astronomical photography, by Mr. William Harkness, of the U.S. Naval Observatory, Washington, D.C. Alluding to Mr. Rutherfurd's special addition of a third lens to his telescope for photographic purposes, Mr. Harkness states that the disarrangement caused by shortening the focus causes so much trouble that most photographers prefer to have a separate telescope constructed solely for photographic purposes. He points out a common mistake made in supposing the focus of the telescope to be changed by disturbances in the atmosphere which frequently break up the images of celestial objects so that it is impossible to see them. The focus never changes, he says. He explains why a sharp photograph of the moon cannot be obtained with Stevens's telescope. All the available counterbalancing powers of curves and differing densities of the glass are absorbed in important corrections for visual accuracy, and, in consequence, the spherical aberration of the blue rays remains uncorrected; hence a sharp photograph cannot be taken by the instrument. Mr. Harkness also states that attempts to photograph the moon with the twenty-six-inch Washington telescope has been a failure, and he predicts that like failures will attend all similar attempts with the great Lick telescope. In short, he says:—"The principles upon which all these instruments are constructed render them incapable of doing first-class photographic work when used with anything like their full aperture. To prevent misapprehension it may be well to add that, as the spherical aberration varies as the square of the aperture, passable photographs may be made with any telescope if a cap is put over its objective to reduce the aperture sufficiently." This paper is as excellent and instructive as it is brief.

We have only space to note a discussion at the Chicago Photographic Association upon the use of coloured media in the dark room for modifying the light during development. They were evidently founded on Mr. W. E. Debenham's experiments, but cannot be properly compared with them, as they did not observe his conditions nor use his actual materials. A large number of colours were tried, from blue to orange, to test both visual and actinic transparency. There was the usual discrepancy of opinion, and one gentleman courted and obtained a smart rebuff when he asserted that he had exposed a plate for ten minutes to the light from a lantern turned on to the full and protected by a sheet of green and one of orange glass. The members remarked it was a poor advertisement of the rapidity of the particular branch of plates tried.

We conclude by giving publicity to the latest discovery of photography, announced on the authority of the *Chicago Tribune* of January 30th:—

"*Cleveland*, January 28.—Edward W. Fell, of this city, after experimenting for two years, claims to have succeeded a few days ago in perfecting an invention, which the author ranks with the electric light and telephone. The invention consists of taking absolutely-permanent pictures upon any substance whatever having a smooth surface, instantly by the action of electricity upon a sensitive coating, and at an expense not exceeding one cent per picture. A reporter who called upon the inventor was shown some photographs on pieces of wood, which were not only perfect in outline and finish, but possessed a peculiar softness not obtainable by any other process."

ON THE PERMANENCY OF SILVER PRINTS.

[A communication to the Newcastle-on-Tyne and Northern Counties' Photographic Association.]

From the discussions now taking place at the various photographic societies, and in the journals devoted to photography, anent the fading of silver prints, I infer that the subject has come so prominently forward again from photographers finding a greater disposition in modern prints to fade than was the case formerly. The cause of this rapid fading must be rather far to seek, or some satisfactory elucidation would ere this have been put forward. Must we, then, be content to receive as an axiom the saying that "silver prints *will* fade?" Well; yes. They will, and so will engravings and every other production with paper for its base. But the difficulty is the short space of time photographs too often take to reach this stage. Many of us have photographs by us of twenty years' standing as good as when first produced, and examples of which I will show you, while others but a few months' old are passing rapidly away. How are we to reconcile this discrepancy? To what influence does the one owe its preservation and the other its decay—yet both equally, carefully, or carelessly kept? I would be glad if I could tell you. I can only offer a few remarks on the subject.

From the discussion and opinions promulgated by the earliest workers in photography one is lead to infer that the permanency of silver prints was more favoured by the old *sel d'or*, or mixed hypo. and gold bath, than by the present alkaline toning method. But is it so? As an old worker, both in the printing and albumenising, I trust I may venture to add my mite of information to that already laid before us through the medium of the photographic publications.

I am of opinion that the permanency of silver prints is only in favour of the *sel d'or* method of toning and fixing at one operation when certain conditions are observed, and those conditions exercise an influence upon the permanency of silver prints by any of the methods of toning. I have known prints to fade quite as rapidly when toned by the *sel d'or* bath as by any method subsequently introduced. The first of the conditions essential to permanency I consider to be the use of perfectly-fresh albumen, with nothing added thereto but the necessary chloride, whether of sodium, ammonium, or barium, or a mixture of these according to the required time of the prints. There is no question that the use of fresh albumen in the preparation of paper entails more labour in beating up, and greater care is necessary in coating the paper; the glass, too, may not be so smooth and high as that produced by stale albumen. These considerations, perhaps, may account for many manufacturers of albumenised paper using albumen in a state of fermentation, or, as we may judge at times by the perfume of the paper, in an advanced stage of decomposition.

Looking at the constituents of albumen, does it not stand to reason that if in the very first stage of our printing operations we use a material in a state of decay we introduce the elements of that decay into our photographs? I think this point may be satisfactorily proved thus:—Take two sheets of paper—one prepared with fresh albumen and the other with albumen that is in a state of decomposition, sufficiently so as to be unpleasant to a person with a delicate sense of smell. Sensitise these sheets on the same silver solution. What is the result? The paper prepared with the fresh albumen will retain its purity for some time. I have known it to keep a week in cold weather, while that prepared with the stale, according to the extent of the decay, turned yellow before it was dry, or very shortly afterwards. Take prints from these papers, toned by any method you please, and I will venture to say that the prints on the latter or decomposed albumen will soon be in the "sear and yellow leaf."

The next consideration is the toning bath. There are two drawbacks to the use of the mixed hypo. and gold bath. The first is its apparent extravagance, and the next the difficulty of knowing when you have left off toning with gold and begun toning with sulphur. Thus, it often happened that when a larger batch of prints was toned in the same bath than the capacity of the bath could possibly tone with gold, part of that batch would be in a condition to fade on the least provocation, and often without it. But you must remember that the votaries of the art in those days had not the means of information at their fingers' ends the present generation has. Photographic chemistry was at a very low ebb, consequently errors were committed that we should not be guilty of now. Yet, with it all, work was produced by a few able hands that would bear favourable comparison with the work of the present day, as my recollection of the first exhibition of the Parent Society enables me to say.

To return, however, to my subject. As to the extravagance of the *sel d'or* bath: that is more apparent than real, as by a very simple method all the gold not taken up by the prints can be recovered. The process is an interesting one, and made pleasurable at the finish by the large percentage of metal recovered. The whole process of recovery has lately been treated in a very exhaustive and able manner by Mr. F. W. Hart, so that I need say nothing on that head.

Of the alkaline methods of toning I certainly give preference to the carbonate of soda bath, as, although not, perhaps, giving the richness of tone the acetate bath does, I am inclined to think, by comparison, that the prints are more permanent; and were the gentleman whom I have the pleasure of nominating for membership present he would be able to fully bear me out in this statement both by precept and example. This bath you must make up freshly each day—presuming you tone every day, or, if not, a few hours before use; and that I take to be in its favour, as I consider a bath that has been used over and over again must necessarily carry some impurities with it. As the undeposited gold can be precipitated with sulphate of iron there is little gain in pushing a bath to the utmost of its powers.

The next consideration is the ready-sensitised paper, and whether its introduction is in any way answerable for the fading of silver prints. I have been led to the conclusion that it is. The accusation is sweeping, I admit; but as it is founded upon practical experience and not on theoretical reasoning—theory and practice not always agreeing, especially in photography—I shall stand by my statement until refuted by the comparative experiments of others. It has been our custom—rather an apathetic one—so long as a paper would "keep well, print quickly, tone easily, and yield prints of good quality," to be content, giving no thought to the morrow of such prints.

The method of toning the mounting medium and the quality of the mounts have been from time to time put forward as the delinquents in bringing about fading, and albumen more than once has been pointed out as the culprit; but a bill of indictment has never, to my knowledge, been preferred against durable sensitised paper. Well, it is done now, and, therefore, the sooner you constitute yourselves a grand jury to inquire into its merits the better, and if you are unable to return a true bill my experience will not be verified.

We must bear in mind, when making comparisons between the permanency of prints of the present day and those of the past, that in the earlier days of photography absolutely fresh albumen was considered imperative in the preparation of paper—so much so, that each egg was broken singly into a cup in order that its freshness might be assured before being added to the bulk.

What is the moral of the little I have had the privilege of saying? Firstly: that if you wish to secure the greatest amount of permanency in your prints use paper that has been prepared with absolutely-fresh albumen, with nothing added but the salting medium. Secondly: whether you tone by the *sel d'or* or one of the many alkaline methods, do not overwork your bath. Thirdly: watch the behaviour of your ready-sensitised paper. Lastly, and this is only a hint: finish washing in several changes of warm water.

Bear these items in mind, and I think there will be less cause to complain of the fading of silver prints. R. STANLEY FREEMAN.

LECTURES AT THE ROYAL INSTITUTION.

PHOTOGRAPHIC ACTION.

THE third lecture was delivered at the Royal Institution on Saturday last, the 15th instant, at the commencement of which Captain Abney referred briefly to the concluding remarks of his previous lecture, showing the method of the building up of an alkaline-developed image. He completed his remarks on this branch of the subject by saying that it was not a chance medley of events which caused an image to develope, but the small molecular energies that, when directed judiciously, lead to a practical building up of the edifice; and that the deposition of crystalline matter can be made to be the scientific mode by which an alteration in the composition of molecules can be made manifest. The use of sensitisers as halogen absorbers was briefly dealt with experimentally, as also the unity of the photographic image and the visible image.

The lecturer next referred to the effect of shearing stress on molecules, illustrating his results by experimenting, and showing slides which referred to his latest researches in the matter.

The intensity of radiation was next dealt with, and the apparent failure of the law which is usually enunciated that exposure multiplied by the intensity, if a constant quantity, should always give the same effect on the molecules. A plate was exposed, about one foot from a blue Bunsen flame, for thirty seconds, and another to the spark emanating from five Leyden jars, the relative times of exposures being stated to be 7,500,000 to 1, whilst the volumes of illuminated gas were as 1,000 to 1. Thus the quantity of illumination multiplied by the time of exposures would be as 7,500,000,000 to 1, which would mean an intensity of light in the spark far exceeding that which it really possessed.

The subject of the destruction of the effect of light on the molecules, by means of oxidising agencies, was next thoroughly gone into, and several experiments and slides were exhibited, showing the effect of bichromate of potash, peroxide of hydrogen, and iodine as destructive agents.

The action of light in aiding oxidation was next experimentally illustrated. A plate of bromide of silver, first exposed to light, was immersed for a second in a solution of bichromate of potash, and then exposed behind an opaque plate with a cross cut out of it, so as to be transparent. The sensitive plate, to which the bichromate was still clinging, was then developed; and the audience saw on the screen the parts of the plate which had received the second exposure continue unaltered, whilst the remainder blackened all over.

The lecturer made some final remarks on the struggle which always was carried on between the reducing action of light and the oxidising action. The whole of the experiments were most successfully performed.

Mr. C. Ray Woods managed the lantern for the lecturer, as also the electrical portion of the experiments. Captain Abney's well-known proclivity for "red coats" made it a matter of course that his assistant should be one of them, and Sergeant Jackson, R.E., was everything which a lecturer could wish.

PHOTO.-BLOCK PRINTING.

[Abstract of a Lecture delivered before the London and Provincial Photographic Association, by T. Bolas, F.C.S.]

The process of printing in a typographic press from a block produced from a photograph is a method of great interest to every photographer. Silver printing, however beautiful the results obtainable, is open to the charge of want of permanence, and, where large numbers were required at a moderate cost and with rapidity, was quite out of the question. Some time since a well-known photographer was asked what was the printing process of the future. He replied "photo.-block printing." He was probably right.

The process of printing from a raised block is now thirty years old, but it is only lately that such modifications and improvements have been introduced as to give promise of its coming into general use. There are now so many variations of the method known, each of which may be called "a process," that to enter fully into details concerning all of them would occupy not one lecture, but twelve or twenty-four. It is, therefore, only practicable to speak of a few of them.

Between twenty-eight and thirty years ago Paul Pretsch came from Vienna with a process which, with the perseverance characteristic of a great man, he had worked out and brought to a certain degree of perfection. This process was based upon the reticulation which a film of gelatine combined with bichromate of potash undergoes when dried at a temperature sufficiently high and exposed to light. This grain is modified by the degree of exposure to light, and so rendered capable of producing a block with a natural stipple or grain due to the reticulation of the gelatine. An illustration of this method appears on page 80 of the current vo'ume of the *Year-Book*.

The Pretsch process has not been worked to any great extent commercially, and when the company which had been formed to work it "came to grief" it was doubtless because it was before its time. Soon after the collapse of the Pretsch Company Mr. Dallas (who had been connected with it) started making blocks on his own account. From the specimens that have been shown, in which the lights and shades were reproduced in what is known as the reticulative grain, it is probable that the method is to an extent similar. A weakness in the Pretsch method is that the surface of the block is not absolutely plane.

The processes in more general modern use depend upon the fact that a stone prepared for lithography, or a sheet of metal upon which a fatty-ink design has been traced for use as a zincographic plate, can be converted into a raised block suitable for typographic printing by treatment with dilute nitric acid. This dissolves away the stone or metal in those parts not protected by the ink, and leaves them as raised lines. If the action of the acid be uninterruptedly continued sufficiently long to obtain a high relief, such as is required for the printing-press, the fine lines will suffer or be destroyed, and for this reason—the acid acts in all directions, and as soon as there is a perceptible depth eaten away the sides of the lines will be dissolved as well as the space between them. To obviate this difficulty, as soon as the plate has been eaten away to a very slight depth, the acid is poured off, the plate washed and re-inked, and the lines being loaded up with ink and resin the plate is warmed. The resin runs a little down over the sides of the lines and so protects them while another etching is performed. This is repeated until sufficient depth is obtained.

It will be seen, then, that the first essential matter in these processes is to obtain a photograph in fatty ink, the half-tones of which must be represented by a grain, by dots, or by lines. Some of the methods of producing such lines or stipple, illustrating the processes dependent upon such methods, will now be described. Hundreds of processes must be omitted, and those now treated on all depend upon the translation of a Woodbury relief into such a representation by line or dot of the half-tone of the original as has been found to be necessary.

An ingenious method of translating the gradations of a Woodbury relief into stipple was devised by Mr. Ives, of Philadelphia. An inking roller is used to enter the deep places in the gelatine, and the mould or relief is inked all over with this roller. A paper has been prepared which has been rolled into a pyramidal grain. The size of the grain may vary somewhat, but in the specimen shown the tops of the pyramids are about the hundredth of an inch apart. This paper is laid upon the inked relief, and is placed in a press. The greater pressure exerted by the prominent places in the relief causes the pyramidal grain to be filled up to the bottom or nearly so, whilst in the half-tones the pyramids will be inked to a less depth and in the high lights not at all. Thus the half-tone of the Woodbury relief has been translated into a sort of mechanical half-tone by dot or stipple. [The lecturer here performed the operation described, using a velvet roller and a small screw press.] In actual practice a hydraulic press is used, and the relief placed between accurately-true surfaces. It is not practicable or necessary to bring such appliances to this meeting. It will be understood that it is only intended to show the principles concerned. [An example of the translation by this method of the Woodbury relief into a raised zinc block was passed round, together with a print from the same.] This print was one of a number made with an ordinary printing machine at the rate of about twelve hundred an hour, and the result was good enough to illustrate the fact that a process of this character has a large commercial future.

Other methods of translating half-tone into dot or stipple have been devised. Very fine results have been obtained by Meissenbach, an example of whose work I now pass round. There is a good deal of quality in this production, but we must not expect to get at once every advantage. When block printing has been worked and studied as much as silver printing a still higher quality will come.

Three methods of translating the Woodbury relief into stipple have recently been patented by Zuccato. In the first of these methods V-shaped lines or grooves are ruled in type-metal, the metal is then inked, a piece of paper is laid upon it, and the relief on the back of the paper. Under pressure the paper is forced more or less between the lines, and takes up more or less ink according to the thickness of the various portions of the gelatine relief. In the second of the Zuccato methods a piece of gauze is used between the paper and the inked metal; and in the third method the metal block is covered with a pattern inked in dot or stipple. The pressure of the raised parts of the gelatine relief behind the paper caused the dots to be spread out, their magnitude and consequent closeness to each other causing the shades to be deeper.

Mr. W. B. Woodbury has devised several ingenious methods of translating half-tone into stipple. Some of these methods are patented. In one method he backs up the negative with gauze, so as to produce a grain in the relief itself.

OLD PHOTOGRAPHS.*

Permanence and the Causes of Fading.

The *permanency* of photographs has always been a thorn in the side of the photographer, or, I should rather say, the want of permanence. With all the improvements in apparatus, uniformity in chemicals, and experience the charge of want of permanence is quite as much and quite as fairly used as a weapon in the hands of its detractors, and even of its friends, as ever it was. If anything, I believe modern silver prints are, on the whole, less permanent than old ones. The reason is understood by most who have had experience in the matter, and is, I think, fairly attributed to the more delicate negatives and less-concentrated solutions used now than formerly, especially the thinness of the negatives. There seem to be a few well-ascertained causes of deterioration of silver prints, scarcely any of which are irremediable. They are—1. Very rapid printing from thin negatives. 2. Imperfect fixation, including imperfect removal of the salts formed by the process. 3. Insufficient washing or bad quality of the paper. With regard to the first reason—"quick printing from thin negatives"—the remedy is obvious. With regard to the second, which is by far the most serious fault of any, the remedy, although obvious, is not so easily applied, *perfect* removal of the unstable matter from the paper being somewhat troublesome to thoroughly effect. This arises in a measure from having uncertain quantities to deal with, the methods of procedure not being varied accordingly. A plan that will answer with one sample of paper at one time will at another, with a different paper, fail. The temperature, also, at which the process is worked has a considerable influence upon the results.

The following conditions, I am inclined to think, form a rough outline of causes of failure:—An exhausted or a too weak solution of hyposulphite of soda. This may be brought about by attempting to fix too many prints in one quantity of solution, or owing to the hypo. having lost some of its solvent power by being kept in solution and exposed to light, or by the crystals being kept in a moist state; by the salt itself being impure or containing a large percentage of sulphate; or *the silver salts formed by the action of the hyposulphite not being thoroughly removed from the paper* by rapid and effectual washing. I have found by actual experiment *that if the hypo., after having effected the solution and alteration of the salts of silver, be well washed out of the prints, fresh* hyposulphite (say a twenty-per-cent. solution) applied to and left in the prints and dried in the usual way has *no effect* whatever on their permanence—an experiment anyone can make. This, I am aware, runs counter to the general opinion, as it includes the mounting of prints on boards containing hyposulphite, which is supposed to affect their permanence. I attribute the deleterious effects of such mounts to something else than hyposulphite—probably chlorine.

That a strong, hot solution of hyposulphite will effectually fade a silver print there is no doubt whatever, but the cases are not parallel. We might with as good reason say because strong nitric acid applied to the skin will blister it very dilute nitric acid will do the same, only more slowly. This we know is not the case. Therefore, because under certain conditions hyposulphite of soda will be injurious, under different conditions there is no reason to look upon it as prejudicial to the degree it is generally represented. Like many other substances, the effect depends upon how it is applied. Bad quality of paper will cause a degradation of the tones and a yellowing of the whites, but will not cause fading in the true meaning of the word.

* Continued from page 169.

CONFUSION AS TO THE MEANING OF TERMS.

There seems to be some amount of confusion with regard to the term "fading" that is applied indiscriminately to silver prints which have become defective from various causes, when it should rightly be confined to those prints in which the shadows have become less deep than when they were made. With numbers of photographic printers a sort of rule-of-thumb holds good—a certain quantity of hypo. in the fixing-bath, a certain time for the prints to remain therein, without any other variation, so that they are turned over occasionally, and no consideration for kind of paper used or the number of prints to be fixed. The routine is the same, winter and summer, and, like the laws of the Medes and Persians, which altereth not (or had not used to be), the consequence is irregular results. Probably the first prints put into the bath are all right, but the subsequent additions are not so; hence some fading and some remaining good. These causes, operating on prints of different degrees of substantiality, so to say—prints from strong or hard negatives, and those from delicate or weak ones—are quite sufficient to account for the different degrees of permanence. This has, in fact, procured for silver printing the unenviable notoriety of being a fugitive process. In addition to these causes of failure, printing for many years was looked upon as merely an unimportant mechanical process, to perform which almost anybody was good enough. Inexperienced youths were generally employed in the printing department. The mystery is that silver prints lasted as well as they have done; and is it to be wondered at that prints faded, yellowed, and had all sorts of complaints, when operations requiring a considerable amount of technical skill and chemical knowledge were deputed to such incompetent hands, so utterly ignorant, and, as a rule, careless as ignorant? It only remains for photographers to be conscientious and careful to remove this stigma from an art the results of which have never been surpassed by any other mechanical or chemical method of printing, and, in all probability never will be.

I have as yet said nothing about toning as an influence for the preservation of silver prints. That it exercises a good effect to this end there is no doubt; but that it is absolutely necessary is doubtful. That prints which have been toned in the old hypo. and gold bath have remained in good condition up to the present time we have proof of here tonight; but whether, in some instances, the toning resulted from the action of gold or sulphur we are not so absolutely certain. Possibly, if after the toning the proofs had been subjected to a fresh hypo. bath, the result might have been much better. In our present methods of working with the alkaline gold bath we certainly do get a deposit of gold on the image, and the colour resulting therefrom is pleasant to look upon. Basing our opinion on the respective qualities of the two metals (gold and silver) to resist atmospheric influences, the superior permanency must be accorded to gold. This, with the decided improvement in the appearance of the picture will, no doubt, cause us to retain the use of the gold toning bath so long as silver printing continues to be the process in general use. EDWARD DUNMORE.

(To be concluded in our next.)

THE CHADDERTON EXPLOSION.

WE have condensed from the *Oldham Evening Express* the following report, omitting from it such matters as were devoid of technical interest:—

The adjourned inquest on the body of William Heywood, the boy who was killed by an explosion at an entertainment given in the Chadderton Town Hall, on the 22nd ult., was resumed on Monday last, in the Chadderton Town Hall, before Mr. Molesworth, coroner. The wrecked apparatus was temporarily fixed in the room, in order that the matter might be better explained to the coroner and the jury.

The Coroner, after the jury had answered to their names, said since the last sitting of the inquest he thought it right that they should know what had taken place, and what he had done with a view of saving the time of the jury and the witnesses. He had seen Mr. Diggle, and had taken from him a considerably lengthy deposition, which he would read to them. He also said that he would forward the facts of the case to the Home Secretary, requesting that an inspector of explosives should be sent down. He had received a reply to that letter, in which Mr. A. F. O. Liddell, on behalf of the Home Secretary, stated that he thought it was a case in which it was not necessary and would not be of any advantage to send down an inspector. Since then he had taken the statement from Mr. Diggle, and which had appeared in the papers. As certain portions were somewhat vague, he thought it would be a convenience to the jury to have an expert present, and whose opinion would carry some weight and lead them to ascertain the cause of the disaster now under investigation. He had therefore seen Professor Roscoe, who would be able to give every information for the assistance of the jury, and whose advice might lead to the prevention of similar explosions.

Mr. Diggle was then sworn, and in reply to the Coroner said he had used the ether-oxo gas about three months. He had used it about thirty times in all. He had two generators, one being horizontal and the other vertical. The horizontal one was made entirely of brass, and the other of brass and glass. He had the horizontal one connected on his return into the room after he had been to fetch the weights, but he could not get the burners to light. He then found that the ether generator had not been charged with sufficient ether at the time the horizontal generator was connected with the oxygen bag and the lantern, but the tap connected with the bag was closed. He then went for some ether, and found that another bottle in which he had some was empty. He therefore knew there must be something wrong with the horizontal generator. He then took down the vertical generator and removed the horizontal one, and put it in its place, and charged it with ether. In the afternoon he had been trying the lantern and generator to see that they were right, and after trying them he thought he must have taken the ether out of the small bottle he had got for that purpose, as when he went home he found it was empty. On his return into the room afterwards he thought some one must have been touching it in his absence. He then opened the tap to see if it was right, and connected it with the tube of the vertical generator. He found the lamp burnt improperly, and he asked the party he left in charge of the entertainment during his absence who had been touching the lantern, and he said he did not know. Witness said it must have been touched. He did not then think there was any danger, and mentioned the delay which had occurred in consequence of changing the generator. The oxygen that passed through had to be lighted with a match, and when I lighted it it burned all right. I was not deaf at the time, but I am a little now.—Mr. Mellor: In your judgment would the oxygen gas on the floor rise without pressure? No. At the time of the explosion there was 112 pounds weight on. I put one 56-pound weight on, and I lighted the gas. There was a necessity to put another 56-pound weight on, because one was not sufficient. One 56-pound might turn the pure oxygen on, but I did not try it. The pressure would force the oxygen more forcibly through the ether. In order to do that the one weight was not enough. I have used this ether-oxo light several times. I got the brass generator the week the explosion took place. I got it for the reason that if the glass were to burst the brass was safer, otherwise he preferred the glass one because he could see the ether.—Mr. Mellor: Had you on other occasions found ether in the tube before? No.—Before you connected the pipe with the oxygen bag had you held it up to see if there was any ether in it? Yes.—Did you hold it up on every occasion to see if there was ether in it? Yes.—Why on this occasion? To see if it would light. In my judgment it was safe to use it.—In your judgment, now, was it safe? It was not, but on this occasion it was more susceptible to explode because there was a less vacuum on the bag.—The accident was caused by a vacuum flame rushing down the pipe into the bag? That is my judgment.—And that vacuum was caused by the weights being removed from the bag? My impression is that someone had pushed against the bag and removed the weight; the vacuum would then be caused.

Professor Roscoe, professor of chemistry, said he had examined the apparatus used at the entertainment by Mr. Diggle. He had partly heard the evidence given by Mr. Diggle, and had come to certain conclusions, which he would be glad to explain if they desired it. He had formed an opinion respecting the cause of the explosion. It was evidently due to the admixture of ether vapour with oxygen, which, mixed together in the proportion of six volumes of oxygen and one volume of ether vapour, became a most explosive mixture, and the firing of a bag of the size used filled with such a mixture would be quite sufficient to produce the effects observed. He considered that the vertical ether vessel was much more dangerous than the horizontal one, inasmuch as a small variation in the pressure of the bag might with this arrangement cause a suction of the ether back into the bag, whereas if it were an horizontal ether vessel, by keeping it in its right position, such a back suction could not occur—that was, a suction of the liquid back into the bag. The evaporation of about one ounce of ether into the oxygen contained in the bag would be sufficient to produce the explosive mixture referred to. He wished, however, to express his opinion that this system of using ether, whether in the vertical or horizontal vessel, was one which ought to be most strongly discountenanced. Even with the horizontal ether vessel the operator was working necessarily with a most dangerous explosive mixture in his vessel, and unless the greatest care was taken this vessel might explode the ether, and a most inflammable liquid would then run out and take fire.

The Coroner then read over the evidence of Elizabeth Heywood, which has already been given, and she stated that just before the explosion took place she heard something like the clapping of hands, and this was followed by the explosion. He asked Professor Roscoe if he could explain the clapping of hands?—Professor Roscoe said that was readily explained, and in fact he had rather expected to hear some evidence on that point before explaining.—A Juror said he would like to know whether one ounce of ether would cause the fumes that were experienced after the explosion.—Professor Roscoe said it would produce fully that. He meant to say that a small quantity of ether would produce this effect. He said one ounce of ether evaporated into the bag would form with oxygen this explosive mixture, and would be quite sufficient to produce the effects observed.

Professor Roscoe then explained how the flame would pass through the tube, and in doing so there would be a series of small explosions in the tube before the main explosion, which would account for the noises that had been heard.—By the Coroner: Would the bag being placed on the floor be more dangerous than being on the level?—Professor Roscoe: The position of the ether vessel on the table and the bag on the floor would render back suction of the ether easier than if the vessel had been placed on the same level. My most strong advice is that ether should not be used in any case. The only safe way in using the light is to have the hydrogen in one bag and the oxygen in the other unless a blow-through burner be employed, in which the coal gas can be taken from the ordinary gas main.—Mr. Diggle: How was it possible for ether to get mixed with the oxygen when there was 100lbs. pressure on the bag and the tap was closed?—Professor Roscoe: It is possible that a diffusion might have taken place. The fact that the bag was burst is proof positive that ether or ether vapour found its way into the bag, notwithstanding the pressure on the bag. It was possible for the noises heard to have occurred an hour before the explosion. —Professor Roscoe proceeded to give other technical evidence.—By Mr. Mellor: It was possible that some ether might have been left in the tube after it had been poured out, and it is quite possible that so much ether might be left in the tube as to cause the claps spoken of. If a quantity of ether had got into the bag it would certainly cause an explosion. I condemn the system in any shape.—Mr. Diggle: I should like to know if Professer Roscoe has ever used the light?—Professor Roscoe: No; I should be very sorry to do so.—Proceeding, Professor Roscoe said he had no doubt that if a weight was removed from the bag it would conduce to an explosion.—The Foreman asked the professor his idea about the pressure-board. —Professor Roscoe said sometimes these boards stuck, and weights came off. There was not much danger of the weights falling off.—A Juror: Then how do you account for the vacuum theory? I don't account for it, and I don't understand what Mr. Diggle means by a vacuum.—Mr. Diggle further explained what he meant, but Professor Roscoe characterised it as a "notion."—Juror: You say that there was ether in the bag, and you turned on oxygen to find that out. When you did so was it not possible for some to get into the bag?—Mr. Diggle: No.—The Coroner: If the bag had been above the apparatus would it have been dangerous?—Professor Roscoe: It would be dangerous in all cases.—Mr. Ascroft: Has Mr. Niele asked, on behalf of the society, whether the new gas was as safe as the other?—Mr. Diggle: I cannot say. If he did I told him it was, in my opinion.

Dr. Patterson said: I made a *post mortem* examination of the body of William Heywood, on the 25th of February, assisted by Dr. C. F. Diggle. The body was much discoloured, and bore evidence of having been crushed or squeezed. There were superficial abrasions of the skin, the largest of which was over the left shin bone. There was nothing unusual in the other parts and organs of the body, except in the lungs and heart. The former were much congested and exhibited the appearances usually found in persons who have been suffocated, while the heart bore similar testimony. The cause of the death of William Heywood was therefore suffocation.—By a Juror: There were no bruises or crushes to cause death. I cannot say that death was caused by gas. It was for want of air. A man standing on the chest of deceased for two minutes would cause death. Suffocation by gas could not be detected after death.—By Mr. Diggle: There was not sufficient gas in the room to cause death.

Mr. Joseph Farrer, one of the secretaries of the Oldham Industrial Co-operative Society, said on the evening in question he saw a number of children sitting near the bag, and removed them. They were about a yard away. The front form would be about four feet from the apparatus, and the children would be about a yard from the bag on either side of the apparatus. The machine would be about a yard from the back of the platform. None of the children touched the bag, so far as he saw, and he was in before the children went in. By a Juror: Did you, Mr. Farrer, notice a noise as of clapping of hands?—Mr. Farrer: I did. It is customary for a slight explosion to take place before an exhibition of this sort begins. I asked Mr. Diggle if anything was wrong, and he said someone had been tampering with the taps, and he apologised for being late. I then told him not to be more than an hour, and also said I had turned out a lad who was making a noise. Otherwise the children were very orderly. —Mr. Ascroft: How many children had you present at the exhibition?—Mr. Farrer: About 393 by ticket.—A Juror: Did you see anyone meddle with the apparatus?—Mr. Farrer: No; there was nobody to meddle with it.—Another Juror: If anybody had meddled with it you would have seen it?—Mr. Farrer: Yes.—A Juror: If anyone but Mr. Diggle had touched it you would have seen it.—Mr. Diggle: You did not hear any report of any kind only at the commencement of the meeting?—Mr. Farrer: I did not.

The jury found that the deceased, William Heywood, was accidentally suffocated owing to pressure on the stairs of the Chadderton Town Hall, caused by a panic owing to an explosion of a mixture of oxygen gas and ether vapour at an exhibition there. The jury appended to their verdict the following recommendations:—1. The jury are of opinion that the use of ether-oxo gas should be prohibited at all public entertainments. 2. That a recommendation be forwarded to the Home Secretary that no person shall be permitted to have any exhibition with explosive gas without a license for such purpose being first obtained.

RECREATION IN ART.

[A communication to the Edinburgh Photographic Society.]

To a Society such as this, with its several hundred members, the vast majority of whom are amateurs studying photography for the pleasure it brings, it may not be amiss to turn aside for an evening from the dry bones of *technique* and manipulation to consider in what way photography stands related to other arts as a source of recreation and enjoyment.

To the professional, who has to attend upon the wants of a somewhat captious and exacting public, the practice of photography may be some *few* degrees removed from the domain of pure pleasure. Indeed, if we are to believe the facetious "notes" and "incidents" recorded in the journals from time to time, it would appear that few occupations are more irksome, worrying, and wearying than the photographic portraitist; so that even to him the following remarks may not be without their interest. They are, however, more particularly addressed to the younger amateurs of the Society—to those who, while delighting in the skill of a handicraft, exercising both brain and hand to the utmost, yet look upon the pursuit as a pleasant, rational, and artistic pastime.

It is not necessary at this time of day to urge the necessity for recreation. Every one recognises the need for it; it is one of the prime necessities of civilised life. The more complex society becomes—and anxiety and worry ramifies life in its various relations, commercial and otherwise—the greater is the need of sources of relaxation which shall give rest and change to those faculties and powers that have been, perhaps, overtaxed, or at least kept too long in a state of tension.

Much as we may prize the many advantages we derive from our commercial and industrial modes of life, it is quite unquestionable that these are obtained at the sacrifice of many things which formerly constituted characteristic elements of social life. We have to find substitutes nowadays for the old-fashioned styles of enjoyment, such as the village fair, the jousts and games, the tournaments, and sundry other sports that suited the tastes and the needs of our forefathers.

I pass without mention those purely physical recreations which now rightly form so large a part of every young person's leisure occupation, merely observing in passing that the development of a taste for athletics among the youth of the country is one of the most gratifying and hopeful signs of which I know. It is a valuable antidote as well as a manly protest against the lackadaisical and maudlin sentimentality which prevailed too long, and did much damage during the earlier part of this century.

My special plea is for the higher forms of recreation—in that sphere where not only can our higher faculties be brought into active exercise, but where the light of genius sheds its rays upon our path, revealing the beauty, the grandeur, and sublimity of nature. That sphere is the sphere of art; its seers, its prophets, and its missionaries are the true artists, under whatever name they may be known, and with whatsoever implements or tools they may wield their power.

There is no recreation so beneficial, so much in unison with our constitution, as that which ministers to the imagination. It is of its very essence that it should take us away from the ordinary and daily routine of life. To renew, to create again, to call in a new set of ideas, feelings, and emotions is the object and meaning of recreation, and this can only be accomplished by falling back upon that power of imagery which we possess, and by which we place before the mental eye pictures of things that have no actual existence, but which excite the mind to action as though they were, while the body remains in a condition of dreamy repose. The mind thus finds relief from the pressure of fact by betaking itself to the realms of fancy, and procures alleviation from the burden of matter by throwing itself into the domain of spirit. Nature transformed and idealised by the imagination has been to man his greatest solace and the source of his best enjoyments.

In a lecture delivered in Edinburgh some years ago, on *Artistic Aspirations*, Lord Gifford thus expressed himself on this subject:—"It is a duty as well as a pleasure to cultivate the artistic or æsthetic faculties, claiming, as they do, so large a part of our highest nature. It were no exaggeration were I to say that, taken in its highest, truest, profoundest significance, æsthetic ripeness embraces the whole duty of man. To be artistic was to know, to love, and to rejoice in nature. *That* was artistic aspiration. To know and to enjoy nature was not only man's highest happiness; it was his paramount, sacred, and eternal duty. Although to the artistic mind and heart beauty and joy were found everywhere in nature, yet to attain æsthetic height, or drink deep of its joys, it was necessary that he should avail himself of all the sides of art, neglecting no form or aspect of external loveliness, and seeking the highest glory in the noblest manifestations and loftiest aspirations of the spirit of man."

The fine arts represent the highest work of man's skill and imaginations, including, under that term, music, literature, paintings, sculpture, and the drama.

Each of these branches of art supply exhaustless sources of recreations of the very highest kind. Of the claims of the drama as a source of recreation too much can hardly be said; for, notwithstanding the evil odour which still hovers over the stage, it is undoubtedly a powerful auxiliary in keeping alive sentiments and emotions which otherwise would but seldom come into play. With a more hearty patronage from those who occupy commanding influence in matters of social order and of morals, I think there can be little question that its influence would be greatly for good. The art of the player is one of those that appeal through the senses to the imagination, working on the feelings and the emotions of the spectators in such a way as to bring out a response—a coincidence of sentiment, of sympathy, or of repugnance, as the case may be—giving by that means exercise to many qualities of heart and brain which otherwise might lie dormant. Some of the best men of our time have defended the stage, advocating its claims as a source of instruction as well as recreation.

The object of the painter is to produce impressions; he in a measure is a coadjutor with the poet in "holding the mirror up to nature." He reflects from his canvas his own impressions of external nature—its moods and conditions. What has moved his sympathies, his admiration, his pity, or his disdain he will endeavour to fix upon his canvas; and so we have in a picture a transcript not only of natural objects and conditions, but a series or combination of impressions of these as they affect the *painter's* mind. I have said the painter is a coadjutor with the poet. Is it not true that the poet looks out on nature with a soul keenly alive to its beauties, his whole being strung in harmony with its every mood and grace. To him the twinkling stars tell tales of mystery, the mighty ocean throbs forth a pæan of eternity, the drooping daisy signifies to him a type of modesty, while the grass and the dewdrop convince him of a tender Providence. He is, as it were, an incarnation of nature—a very part of its inner self; its whole wealth is embodied, transfused, and humanised in him. He steps forth from behind the veil that hides creation's inmost secrets, and as a mediator or interpreter divulges them to his kindred. The ordinary mortal sees not what he sees, hears not what he hears, has no experiences such as he has. His communings with nature inspire him with its profoundest truths. His distinction is not merely that he has the power to put his thoughts or impressions in flowing verse, or clothe them in words that charm the ear by their consonance or their rhythm, but because he obtains glimpses of the inner essence of nature that are not vouchsafed to common men.

And so it is in some degree with the true artist. By the aid of his pencil he is enabled to portray to us aspects and beauties of nature which, but for his interpretation, we would have passed unheeded, or but feebly realised. In greater reality than the ancient wizards he conjures up before our waking eyes scenes of beauty and loveliness that entrance the imagination and absorb it in delight.

J. Hutchison Simpson.

(To be concluded in our next.)

SPECIFICATIONS PUBLISHED DURING THE PAST WEEK.

MANUFACTURE OR PRODUCTION OF BACKGROUNDS FOR PHOTOGRAPHIC AND OTHER PICTURES.

THIS invention, by FRANCESCO ANTONIO MARRA, of No. 69, New Bond-street, London, received provisional protection only.

My invention has for object the manufacture or production in an economical manner of a brilliant, strong, and durable background that will show up and prevent fading of photographs, and which is applicable also to indian-ink and other drawings or paintings.

To produce such a background according to my invention I employ metal in a pulverised or flocculent state, which I cause to adhere to the paper or material that contains the picture by means of adhesive material, such as size. In practice I find it advantageous to coat or cover the paper or material containing the picture with size of the kind used by gilders, taking care to exactly follow the outlines of the picture; then I sprinkle or flock the metallic powder or powders or flakes on to the layer of size, applying pressure so far as needful to obtain an uniform coating; after which the whole is slowly dried, producing a strong background of paper or other fabric and metal so combined as to resemble a sheet of metal with a sparkling, roughened surface, and practically imperishable.

Various kinds of metals—such as gold, silver, bronze, aluminium, and others—may be employed according to the result desired to be produced; and by the use of two or more different metals polychromatic effects can be obtained.

PREPARING AND PAINTING PHOTOGRAPHS, PRINTS, OR DRAWINGS TO RESEMBLE OIL PAINTINGS ON CANVAS.

LIKE the preceding invention this one, too, only received provisional protection. It is by ALBERTA MARY FRANCES CASPAR, artist, of 200 and 223, Regent-street, London.

The photograph, print, or drawing selected should be quite dry and fastened face downwards to a drawing-board or table with four drawing-pins. It should then be rubbed with glass or sand paper until it becomes quite thin. The surface of this reverse side must then be spread with an adhesive gum, paste, or glue, and, if a photograph, must be previously soaked with water. The photograph, print, or drawing so prepared is then covered by coarse canvas, and this is pressed and rolled until the fibre of the canvas penetrates and shows through the photograph, print, or drawing. The photograph, print, or drawing, and canvas is then allowed to dry while still fastened flatly to the board or table. When dry the canvas is stretched on a stretcher. After the canvas is so stretched the picture is clearly shown thereon, and must be painted with transparent albumen colours mixed with water or a water medium, coarse touches of body colour being freely used to add to the illusion. When the picture so painted is dry a coat of varnish can be applied to the whole surface of the picture, which will then be ready for framing.

The novelty consists in—1. The preparation of the surface of the photograph, print, or drawing so as to admit of the canvas showing through it. —2. The pressing or rolling of the canvas upon the prepared photograph, print, or picture so that the canvas shall be seen through the same.—3. The painting in transparent albumenous colours in water, which produce upon the canvas so prepared as aforesaid the resemblance of oil paintings.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Association held on Thursday, the 13th instant, the chair was occupied by Mr. A. Cowan.

The presentation to the Association, by Mr. J. Burgess, of Lommel's *Nature of Light*, international scientific series, was acknowledged.

The evening was set apart for one of the monthly "lecturettes," which, on this occasion, was delivered by Mr. T. Bolas, F.C.S., on the subject of photo-block printing. [See page 185.] Mr. Bolas illustrated his observations by experiments and by examples of the various processes under consideration.

Mr. W. M. AYRES said that when Herr Pretsch was in England he did a good deal of work for him. He thought that if silver printing was properly performed the results were permanent, if only sufficient gold were used.

Mr. BOLAS remarked that the value of Pretsch's services were now better appreciated, and that a monument had recently been erected to him at Munich.

Mr. J. BARKER wished to know how the gelatine relief should be made.

Mr. BOLAS replied:—Take one part of soft gelatine—say Nelson's flake—swell, and dissolve it. Add one-fourth of its weight of sugar and one-sixth part of bichromate of potash. Paper should be coated with this mixture to a thickness of two millimetres. It was essential for the film to be of such thickness that it should not be hardened all through by the action of light. After exposure under the negative the film is wetted, squeegeed on to glass, and the paper removed and relief developed by hot water, the same as in the carbon process.

Mr. BARKER wished to know whether a composition roller of glue and treacle would serve for inking the relief.

Mr. BOLAS said that it would not be suitable. There should be no moist surface to come into contact with the gelatine relief.

Mr. A. L. HENDERSON inquired what would be the result of using a hard, cutting substance and pressing that into the relief.

Mr. BOLAS said it would make a mould that would give an intaglio but not a typographic block. The Goupil process of producing photolithographs was believed to be based upon that method.

Mr. A. J. BROWN wished to know what was the best cutting medium.

Mr. BOLAS replied that the best was hard glass—bottle glass crushed fine. It was an article of commerce.

Mr. BARKER said that he had made some experiments with glass paper and obtained nice results.

Mr. HARE inquired how the Sprague ink-photos. were produced.

Mr. BOLAS replied that it was generally understood they were printed from a lithographic stone.

Mr. BROWN remarked that these pictures showed a grain resembling the reticulation of a carbon print.

Mr. BOLAS said that that was "Pretsch grain."

Mr. J. T. TAYLOR remarked that Mr. Winstanley, many years since, invented a method of obtaining a block by using a set of needles, the points of which were let down into the relief. They were then firmly clamped together and the ends ground off until the points of those which had been least prominent were just reached. A series of dots was thus obtained varying in size with the depth of the various parts of the relief. He thought it a most ingenious invention, but had not heard of its coming into commercial use.

Mr. BOLAS said that a gentleman had long ago consulted him as to the practicability of carrying out Winstanley's invention commercially, but on going into the calculation it was found that the enormous number of needles required would make the cost prohibitory.

Mr. HENDERSON referred to a process of Bullock's, which was of about twenty years' standing.

Mr. BOLAS believed that it was practically identical with that of Sprague. The two photographic journals in 1866 contained illustrations of Bullock's process.

Mr. A. MACKAY wished to call attention to an advertisement and circular representing that the —— Company were prepared to instruct and find employment in colouring photographs for persons not possessing artistic knowledge. The circular called attention to a woodcut representing an imposing-looking building, and professing to be the offices of the —— Company. He went to see what was the art, and found that at a side entrance there was a notice that the —— Company had an office, which at last he reached after mounting many flights of stairs. The process appeared to consist of dabbing on oil colour with the tips of the fingers. The results the members could well imagine, and would understand how far the representation that the purchase of a twelve-and-sixpenny box of colours—said to be specially prepared, but bearing the name of a well-known maker, and worth about five shillings—would enable the purchaser to obtain employment from photographers was likely to be realised.

Mr. W. COLES said he had reason to believe that ladies had been induced to part with their money under the belief that they would be able to earn a living. One had lately called upon him and shown specimens produced in this way. Of course he had told her that no photographer could make use of such work, and that if she really wished to make money at colouring photographs she must learn and practise in the usual way.

Mr. BARKER thought it a duty to humanity that such proceedings should be exposed.

The meeting concluded with a hearty vote of thanks to Mr. Bolas for his lecture.

The next "lecturette" will be given on the 10th of April, by Mr. W. E. Debenham, *On Lenses*.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

A SPECIAL Board meeting of this Association was held on Wednesday, the 5th instant, at 181, Aldersgate-street. The minutes of the previous meeting having been read and confirmed, Messrs. Muller and Collins were elected members of the Association.

The list of members requiring situations and correspondence was then submitted.

The following alteration of Rule IV., clause 1, was then proposed by Mr. ASHMAN and seconded by Mr. GANLY:—"That subscriptions shall be 10s. per annum, payable quarterly, half-yearly, or yearly, which shall entitle the subscriber to one vote at general and special general meetings, and also at each election of pensioners." In the same rule, line 9, it was proposed that the word "benefit" be struck out.

Mr. W. M. ASHMAN, speaking in support of his proposition, said the existing rule did not allow an honorary subscriber to receive assistance should misfortune overtake him. That he considered a mistake, and to his knowledge it deterred some of the profession from supporting the Association. He had no fear that by removing the distinction between the classes those gentlemen who had hitherto ranked as honorary members would withdraw their support. The proposition gave them the option of being donors, or donors and members. He would like to see them enrolled as members, and the balance of their usual subscription considered as a donation. At the same time it would enable those whose position was not fully assured to feel that in case of need they would be entitled to the support which the Society could render. Again: the reduction of the subscription would enable the assistants who could not afford to pay the yearly subscription in one sum to do so by two payments of 5s. or four of 2s. 6d., as circumstances would permit. This he believed would considerably augment the strength of the Association, and that most desirable object having been attained the success of the Society was certain.

Messrs. Ganly, Hall, Thorne, and others spoke in favour of the proposition, which was put to the meeting and carried unanimously.

Mr. Collins, son of the late Mr. C. G. Collins, was elected a member of the Board of Management, and the meeting was adjourned.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The fifth meeting of the current session was held in 5, St. Andrew-square, on the evening of Wednesday, the 5th instant,—Mr. W. Neilson, President, in the chair.

After business of a private character, which occupied more than an hour, Mr. J. H. Simpson read a paper entitled *Recreation in Art* [see page], in which, after referring to the great branches of art, and suggestions for recreation in them, he referred more particularly to photography.

The set of transparencies in gelatino-chloride by Mr. A. Cowan were then exhibited.

The Secretary intimated that Mr. A. L. Henderson, on his recent visit to Edinburgh, had promised that he would endeavour to get members an opportunity of examining these beautiful productions, and Mr. Cowan had most courteously sent them. The transparencies were examined with great interest.

Mr. A. Pringle stated that he had had an extended experience with the gelatino-chloride plates, having experimented with them from their first introduction. Their manipulation was so easy and the results so certain that he fancied if he had had failures he could perhaps have given better information as to the working of these plates. He used the dullest diffused daylight to impress the plates, and he could pretty correctly hit any colour he desired. The larger the quantity of citric acid employed in the developer the longer must be the exposure. He found a ten-per-cent. solution of common salt a splendid restrainer, keeping the bright lights beautifully clear. From extended experiments, however, he had come to the conclusion that as yet no gelatine film was capable of yielding such clear and brilliant transparencies as collodion. He thought that for printing on opal the gelatino-chloride was unapproached for beauty. He preferred to develope a red image, and then tone to the desired colour, the result being one of the prettiest things it was possible to see.

Mr. Alexander Matheson had come to the same conclusion, and he found that when transparencies were thrown on the screen, people with a knowledge of the requirements constituting a good transparency invariably selected those in collodion from any kind of gelatine transparency, as being in some sense more acceptable.

Mr. Forgan had only tried two of Mr. Cowan's plates, and he submitted these as the first results of an amateur. They were both successful.

Mr. Fraser had tried several dozens, chiefly for microscopic work, and found them much superior to bromide plates; and so simple were the operations and requirements that he was invariably successful.

Mr. J. M. Turnbull thought those who desired a perfect lantern slide ought to fall back on the old collodio-bromide. In every particular the development was exceedingly simple, and as certain as simple, while any desired result could be obtained with ease, every detail being under most thorough control.

Mr. Pringle entirely agreed with the remarks made by Mr. Turnbull.

Hearty votes of thanks to Mr. Simpson and Mr. Cowan were accorded by acclamation.

Mr. Turnbull exhibited a new slide-carrier which he had picked up in his recent wanderings in the south. He did not know its author, but it was admitted by all present as probably the simplest and most generally acceptable form of carrier for a single lantern that could be found.

Mr. G. Mitchell exhibited a splendid series of views and animal studies, by Mr. Reid, of Wishaw. They were examined with great interest, and much admired.

The Secretary submitted what he had found to be a very useful adhesive material, obtainable at a very low price, under the name of "gloy." He was afraid to recommend it for mounting silver prints, as he had only met with it during the last six weeks. A silver print coated on both sides with the material had not undergone any change during that time; but for every other purpose he thought it greatly superior to the adhesive materials commonly employed. It dried slowly with a minimum of "cockling," and free from unevenness of body. It was very clean in use, practically transparent, and dried with a slight gloss. By the addition of water it could be reduced in consistency and still retain great tenacity, and it seemed well suited for many purposes where ordinary glue, gum, or starches did not always answer satisfactorily. By the courtesy of Messrs. Fraser and Co., he was able to distribute samples to all who desired to test the material. Several questions were asked as to the constitution of "gloy," but the only explanation definitely given was that it was a waste product.

Mr. Fraser said that when potato-starch was boiled in a *bain-marie* for several hours a somewhat similar material resulted.

The Secretary exhibited a new American camera, which possessed several novel features. The 10 × 8 camera with three double slides only weighed about seven and a-half pounds; it was, nevertheless, very strong and rigid. By a beautifully-finished rack arrangement, exceptional length for focussing was available. The bellows were of india-rubber, and all the metal work was nickelled. By an ingenious arrangement the slides could be used vertically or horizontally without altering the position of the camera, and by the simplest of devices the unwitting exposure of the same plate twice was prevented. In reply to a number of questions, the Secretary intimated that Mr. J. J. Atkinson, of Liverpool, would answer queries as to other sizes of these cameras.

After the usual votes of thanks the meeting was adjourned.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.

The ordinary meeting of the above Association was held in the College of Physical Science, Newcastle-on-Tyne, on Tuesday, the 11th instant,—Mr. J. B. Payne in the chair.

The minutes of last meeting having been read and passed, Mr. Andrew Ross, Mr. John Russell, and Mr. J. H. Inness (of Newcastle), and Mr. F. W. Morgan (of Durham) were nominated for membership.

Mr. R. S. Freeman read a paper *On the Permanency of Silver Prints*. [See page 183.]

The Chairman remarked that the subject was of a very interesting character, and that no one was better qualified to speak and write on such a subject than Mr. Freeman. Personally, his own experience of silver printing had been considerable, and he detailed an experiment he had conducted some time ago:—A sheet of paper was sensitised, divided in two, and these halves were printed together to the same depth as nearly as possible under a mask and vignetted. One half was toned and the other not toned. They were fixed together, washed together, mounted together on the same mount, and exposed together to sunlight. The *toned* print began to fade in the vignetted portion, and in three months had faded altogether. He (the Chairman) remarked that this had never been satisfactorily explained.

Mr. J. P. Gibson was opposed to the use of the *sel d'or* bath, and did not agree with Mr. Freeman's remarks on the use of ready-sensitised papers, especially those prepared with albumen in a state of decomposition. He (Mr. Gibson) had used ready-sensitised paper for many years, had always found it equal in quality to the paper he had sensitised himself, and far less trouble. He used a toning bath composed of chloride of gold and washing soda, being careful not to use too much of the latter, and he always took care to have his fixing bath alkaline. Carbonate of ammonia, in the proportion of about two ounces to the gallon of hypo. solution, was used. He thought that damp was chiefly to blame in cases of fading, and some mountants were totally unsuitable. He preferred himself, for mounting purposes, a solution of gelatine with a large proportion of alcohol added.

Mr. E. Sawyer advocated the use of warm water for washing prints.

The Chairman reminded members that the late Professor Marreco, in a paper read at one of the early meetings of the Association, proved, from experiments, that the copious washing of silver prints so much recommended in photographic text-books was quite unnecessary, and that with care the hypo. could be easily, perfectly, and quickly eliminated.

Mr. P. M. Laws deprecated the practice some photographers had of overworking their baths. He always made fresh baths, using as much gold as was necessary and then discarding the bath. He considered that gold was one of the cheapest chemicals they used.

Mr. Proctor (invited by the Chairman) said he had no prints by him. He had, in conjunction with Mr. Swan and Mr. Pattinson, produced many years ago the first prints ever done in Newcastle. They were on plain paper, salted, and sensitised; but they faded very quickly. That was before the introduction of albumen. He (Mr. Proctor) thought very little was known then of the cause of fading, and that they knew very little even now of the matter. The metals forming the tones of the print would be probably in the form of sulphide, and this might eventually turn to sulphate; but, whatever they were, damp and sunlight would favour such chemical changes.

Mr. Freeman narrated his first experience with ready-sensitised paper and the failure (by fading) which resulted. He would not condemn *all* ready-sensitised papers, as he had found some to be excellent in all respects. He (Mr. Freeman) showed, at the close of his paper, a large number of prints of various ages. Some mounted *cartes* of the exhibition of 1862 were excellent. They were toned in the *sel d'or* bath, and mounted, he stated, with a freshly-prepared solution of gum arabic.

On the proposition of the Chairman, a hearty vote of thanks was accorded to Mr. Freeman.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

The tenth general meeting of the session of this Society was held in the Religious Institution Rooms, on Thursday, the 6th instant,—Councillor Robertson, President, in the chair. The minutes of the last meeting were read, and after an addition—namely, the exhibition of a patented camera by Mr. S. D. McKellen, of Manchester, and the thanks of the Society to Mr. McKellen—were approved.

The question-box was then opened, and one of the questions found in it raised a slight discussion, which was not satisfactorily settled, namely—"Does the luminous paint used with Warnerke's sensitometer lose its power through time?"

Mr. J. Parker then read a paper on a *Sky Shade*, invented by Mr. Henderson, of Montreal. As a special article will soon be published on this shade it is not necessary to comment upon it now.

Mr. McGhie then exhibited several new pieces of apparatus, namely, Addenbrooke's instantaneous shutter, giving an exposure as desired from $\frac{1}{24}$th of a second to three seconds, and Cadett's latest studio shutter, the principle of which is a sliding front raised and lowered by the usual air-pressure arrangement. Both worked very well and were much appreciated by the meeting. He also exhibited Samuel's new patent camera, the novelty of which is the dark slide, which may be made to hold any number of plates. It is simply a box twice the size of the plates to be used, with a division in the centre, and a shutter in front of one of the divisions. The sensitive plates, in blackened tin holders, were put into the division behind the shutter. When it was withdrawn a strong spring pushed the plates forward, the front plate taking the place of the shutter. It was now in position for exposure. When the shutter was pushed back again it moved the plate before it into the other division of the dark slide, which projected beyond the side of the camera. This operation was repeated until all the plates were exposed.

Mr. R. DODD then exhibited a combined apparatus for varnishing negatives and distilling water, which he had used constantly with great satisfaction for the last twelve years. It was a flat copper case about thirty inches square and two inches thick, tinned in the inside, and standing at an angle of about eighty degrees. There were hooks at intervals on each side, to which were fastened movable wooden supports for different sizes of negatives. It was heated by steam conveyed through a tube from a small tinned copper boiler heated by gas. A tube in one of the corners drained off the condensed steam, which, if the apparatus be kept free from dust, is chemically-pure distilled water.

The CHAIRMAN then called upon Mr. Andrew Mactear to re-read a paper which he prepared for the Association twenty years ago on *The History of Photography in Glasgow.* [This paper will appear in our next issue.] The communication proved very interesting, as did also the supplementary remarks by several of the oldest members.

The meeting closed with the customary vote of thanks.

GLASGOW AND WEST OF SCOTLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting of this Association was held in the Religious Institution Rooms, Glasgow, on Tuesday, the 11th inst.,—Mr. Hugh Reid, President, in the chair.

The following gentlemen were elected members:—Mr. F. C. Buchanan, Mr. James Harvey, Mr. A. W. Hogg, and Mr. John Sheriff.

On the recommendation of the Committee it was agreed to take a lease of premises for the sole use of the Association, the rooms to be used for meetings, demonstrations, &c., as well as for members wishing to develope, &c.

Mr. W. Lang, Jun., then read his paper *On Bichromated Gelatine Films and the Stannotype Process.* [The MS. of this lengthy communication reached us as we were going to press, but we hope to include it in our next number.] He also gave a demonstration of the whole process of stannotype printing, and threw off a number of prints at the meeting from moulds made by himself. The interest of Mr. Lang's lecture was much increased by a number of very fine specimens of the various bichromated processes and some exquisite stannotype prints—all very kindly lent by Mr. W. B. Woodbury for the occasion.

On the motion of the CHAIRMAN, the meeting awarded a very hearty vote of thanks to Mr. Woodbury for his kindness in sending the specimens, and the same compliment was paid to Mr. Lang for his interesting paper, and for the immense trouble he had taken in getting up his demonstration.

The CHAIRMAN then read a letter of resignation from Mr. Smithells, the Secretary, who is leaving Glasgow, and the meeting passed a unanimous vote of thanks to that gentleman for all his work on behalf of the Society.

Mr. George Murray, 31, St. Vincent-place, Glasgow, was appointed Secretary. The meeting was shortly afterwards adjourned.

BURY PHOTOGRAPHIC AND ARTS CLUB.

THE first *conversazione* since the formation of this Club took place on Tuesday, the 11th instant, at the Temperance Hall, when a very agreeable evening was spent by about 240 ladies and gentlemen who had accepted the invitations of the members. The windows of the hall were draped with crimson and white curtains, and the gallery had also received its share of adornment, crimson and white being the prevailing colours.

Around the room were placed tables on which were arranged photographs of notable places and choice bits of local scenery, the work of the members, and much of it of the most commendable character. These included views taken in the Fylde district by Mr. C. H. Openshaw, one of the junior members of the Club. Mr. Wm. Booth (Heywood) exhibited views of the Isle of Man, &c.; while a large number of photographs of local and other scenery, including an excellent view of the interior of a farmhouse where John Wesley preached, were the work of Mr. J. Nelson. Mr. W. Palmer contributed an oil painting of the old "White Lion" Inn, Bolton-street, before it was pulled down; and Mr. J. J. Rishton, a member of the Manchester Photographic Society, exhibited a number of views on the Wharf. Views of the district through which the River Wyre flows, Miller's Park, Preston, Prestwich Clough, and other localities, were shown by Mr. R. Grundy, Jun., Parkhills. Mr. H. M. Dearden had no fewer than thirty photographs of bits of local and other scenery, including the interior of the Bury Grammar School. Mr. F. W. Livesey, the Secretary of the Club, contributed twenty-nine views, amongst which were some capital sea-pieces produced by the instantaneous shutter. Mr. W. S. Barlow had several, and Mr. E. Eccles a fine case of portraits. The Rev. J. C. Hordern sent two excellent water-colour drawings, *April on the Yare, Norfolk*, and *Quarry Tramway, Penmaenmawr.* Mr. Shaw exhibited a figure of *Hamlet*, the gift of his friend Mr. Henry Irving, and some portraits of Miss Terry, having written upon the back by that lady an expression of thanks for many kindnesses received. A number of microscopes were contributed by Mr. J. Taylor, Mr. E. W. Mellor (Warthfold), Mr. J. Walmsley, and Mr. J. Nelson. Mr. E. W. Mellor lent some beautiful views of the Bermudas and Eastern scenery, and a pencil drawing of Mrs. Langtry was also shown by Mr. E. Watkin, of Sale.

The PRESIDENT opened the proceedings by briefly giving those present a hearty welcome. He remarked that clubs of that kind were doing a useful work. Young people after leaving school, in order to keep out of mischief, should have some hobby, whatever it might be, for their leisure. It was, therefore, only natural that those having similar tastes should join together and form clubs such as that was. The bulk of the members of the Club had taken to photography as their hobby, but they did not wish to confine the Club to that. They wished to have their taste improved, and desired those to join the Society who devoted their spare time to the brush and pencil, in order that they might be told where they had gone wrong, so that their photographic views might be as artistic as possible. He thanked especially the President and members of the Manchester Photographic Society for attending.

During the evening songs, glees, &c., were given by a number of the members, assisted by several lady friends.

A number of views taken by the members of the Club were shown on a screen by Mr. Walmsley by means of the oxyhydrogen lantern, and in the intervals the guests were supplied with refreshments.

YORKSHIRE COLLEGE PHOTOGRAPHIC CLUB.

THE day of meeting of the above Club having been changed from the first to the last Thursday in every month, to avoid clashing with the Leeds Photographic Society, the third meeting was held on Thursday, February 28th,—Mr. H. B. Hall in the chair.

Professor THORPE, Ph.D., F.R.S., read a paper on ***Platinum Printing***, with practical illustrations.

Previous to this paper being read the terms of the second prize competition were arranged. It was decided to have another competition, all competing pictures to be sent in on or before the day of meeting in May. The subjects selected for the competition were ***A Group, A Cottage***, and ***Spring.*** Three prizes will be given for the best picture sent in of each. This having been settled, the Chairman called on

Dr. THORPE, who commenced his paper by giving the theory, chemically, on which the process of platinum printing is based, pointing out the technical difficulties which had to be overcome. He (Dr. Thorpe) then dealt with the rapidity of printing as compared with silver, and with the increased difficulty of double printing. He also pointed out particularly the limitation of the process, inasmuch as under-exposed or soft negatives, and also negatives with extreme contrasts and half-tones, could not be used. Dr. Thorpe concluded his paper by actually developing some prints to illustrate the process. He also exhibited a number of instantaneous and other pictures, in platinotype, taken in widely-different places, and admirably showed the wide adaptability of this kind of printing if the negatives were good.

A vote of thanks, moved by the Chairman, and seconded by Mr. Gamble, concluded the proceedings, and the meeting was adjourned until Thursday, the 27th March.

Correspondence.

DARK ROOM ILLUMINATION.

To the EDITORS.

GENTLEMEN,—Allow me to correct a mistake that occurs in your report of the last meeting of the Photographic Society of Great Britain. I said that I used *deep* not "*pale*" yellow paper in combination with the green glass.

The manner of setting up your abstract of Captain Abney's paper makes it appear that what was read as part of that paper was expressed by Mr. C. Ray Woods and Mr. J. Cadett in the debate; and Mr. Cadett is represented as being responsible for the statement that exposure at a certain distance gave an image with canary medium, and none with stained red glass. I do not think that that gentleman, or indeed anyone else at all, will undertake the responsibility of such a statement. "Stained red" glass is an article of commerce. I have obtained some from Messrs. Chance's agent, and the amount of photographic power passing through it I have found so much greater than that which passes through canary medium that I am at a loss to understand any experimentalist meeting with any other result. Mr. G. F. Williams, about a year ago, showed at the Photographic Club a wedge composed of increasing thicknesses of stained red glass up to ten, and photographic action had passed through them all.

With respect to a comparison of the visual light transmitted by various media: Mr. Woods' sight appears to be of such an abnormal character as not to afford a fair basis for any general argument. At the technical meeting in January, when I showed my lantern with various coloured media, whilst all others who expressed an opinion considered that the red side (cherry fabric) gave the least visual light, Mr. Woods said that he thought he could see best with that illumination. I am willing to accept Mr. Cadett's estimate of the luminous values of the several media, and should like to see this estimate compared by independent experimentalists with the protective power of the same media, as well as with the combination that I have particularly recommended. If it be found that, with an equal illuminating power, yellow has no more effect upon a sensitive plate than red, the case, as I originally put it, is established; and there is no necessity for the employment of a light which is certainly in many cases injurious to the sight. The experiments of others, however, appear to show much more than this.

Captain Abney is further reported as stating that green glass only cut off such rays as were harmless. In another report I find Mr. C. Ray Woods stating that Captain Abney had not used the glass I employ and recommend, but one of a "better green for the purpose." Surely these gentlemen "protest too much." If the "better one" only cut off harmless rays, does the one I use let through more photographic power than would pass without it? As a matter of fact, yellow-green glass *does* cut off considerable photographic power, especially when used in conjunction with deep yellow. When a moderately-safe amount of yellow medium is used a considerable additional thickness of the same medium does not cut off the active light so well as one thickness of green glass, whilst the latter takes the heating effect of the red and orange rays out of the light, and preserves or restores its yellow colour.

If the Council of the Society permit, I propose to show the results of some experiments with the media in question at the next regular meeting, before the commencement of the lantern display.—I am, yours, &c.,

March 18, 1884. W. E. Debenham.

MUNGO PARK *versus* MUNGO PONTON.

To the Editors.

Gentlemen,—Allow me to show you by the enclosed page of my work on carbon printing that I give the right name—"Mungo Ponton." Mr. Ponton was the first to point out the photographic properties of bichromate of potash, as early as 1838. He immersed well-sized paper in a solution of this salt and dried it by the fire, and exposed it under an engraving to sunshine, whereby a yellow print upon a brown ground resulted.—I am, yours, &c., E. Liesegang, Ph.D.

Dusseldorf, March 15, 1884.

TOURISTS' REQUIREMENTS.

To the Editors.

Gentlemen,—I am one of those who think that tourists' requirements are very badly met by manufacturers, especially in the waste of their time over each view in making the multifarious adjustments of the present travelling cameras; but now I write on another point. The weight of glass plates greatly reduces the quantities sold for tourists' purposes. If they were of the thinnest glass, and if the slides were reduced in bulk, I should use 100 plates per month more than at present; but with the present plates I cannot increase the weight of the apparatus, as it would then be too heavy to carry comfortably without a porter.—I am, yours, &c.,

Lucerne, Switzerland, March 12, 1884. W. H. Harrison.

SODIC SULPHITE.—FINAL.

To the Editors.

Gentlemen,—I was unable, from absence, to reply to Mr. Berkeley's article last week. I beg to assure him I do not in the least ignore his undoubted claims to early publication of the value of sodic sulphite. Quite the other way. But there is just this point of difference, that whereas he tells your readers it can be bought at his place of business, and distinctly declines to say how it is made, I gave full and detailed instructions for making it up. It is true it can be made with cold water, but not so surely as to getting a saturated solution as with hot.

I was a little puzzled, on reading the earlier portion of Mr. Berkeley's article, to know what was the real cause of his intervention in the discussion; but I soon came to that part where he says he notes gratuitous advertisements are to be had in your Journal, and then proceeds to at once secure the advantage of an excellent one for his house of business. I am far from censuring him for this—quite the reverse. I assure him I fully recognise his services in pressing on public attention the use of sodic sulphite, and that I have no desire at all to diminish his perfectly-just claims.—I am, yours, &c., Samuel Fry.

Surbiton, March 19, 1884.

[Mr. H. B. Berkeley first pointed out the properties of soda sulphite in our Almanac for 1881; in the following volume he gave a definite formula, in which the employment of warm water is recommended. Mr. Fry's subsequent directions, during 1883, to use hot water can have no special advantage beyond securing a saturated solution more rapidly. Mr. Berkeley's formula leaves the operator independent of the uncertainties of a "saturated" solution.—Eds.]

MOUNTING LARGE PHOTOGRAPHS.

To the Editors.

Gentlemen,—The following method of mounting large photographs may be new to many of your readers. We have used it for more than fifteen years, and know of no better way.

If large photographs are mounted *damp* and with starch the expansion and contraction are so great that the mount is "cockled." The correct principle is to mount the print as dry as possible. First have the prints in a pile, nicely damp, and flat. Glue with fine, clear Russian glue and a flat hog's-hair brush, and spread each print out face down to dry. When dried they may be trimmed and kept any time until required for mounting. To mount: have about twelve half-sheets of thick blotting-paper. Place two dry sheets at the bottom, then one well-damped sheet next; lay (say) twelve photographs on this sheet in a pile, and place another damp sheet on the pile. Have one more damp sheet above, and then the rest of the dry sheets. Now take out the top photograph and place it between the two top damp sheets. This is merely to take the hardness out, and the print must not remain long enough to allow expansion. Take it out (putting the top one of the pile in its place), and place it on the top dry sheet. Now sponge it all over with a fine sponge from the middle to the ends, taking care to wet it all over; it must be merely damped, and with as little use of water as possible. Take it up and lay deftly in its place on the mount, smoothing it out from the centre of the print; now take a sheet of paper and a handkerchief and rub it down from the centre to the edges.

It is better to have a flat burnisher at hand to smooth any unevenness. If the print have been nicely mounted and with no unnecessary damping it will soon dry, and, even if only in a paper book, the "cockling" will not be much. The glueing must be thin and even—something of the nature of the gum on a postage stamp. The sheets of blotting-paper will require re-damping if a number of photographs pass through, and it is not well to wet too many on the top sheet without changing it, as the paper is apt to fray up, and small pieces will then stick to the glue and make the finished picture uneven. Keep a basin of clean water on the table and a plate for the sponge.—We are, yours, &c., Robinson and Thompson.

Liverpool, March 19, 1884.

THE MANCHESTER PHOTOGRAPHIC SOCIETY.

To the Editors.

Gentlemen,—In your report of the proceedings of the Manchester Photographic Society, at its February meeting, published in today's Journal, a mistake has been made as to what I said in commenting on Mr. Rishton's excellent paper.

What I said was that when a camera had to be tilted enough to necessitate the use of a swing-back a more truly proportionate picture would be obtained by the concurrent use of a swing-front than without it, because by its use the parallelism of the front and back would be maintained, and the axis of the lens would be perpendicular to the sensitised plate. This, of course, is contingent on the supposition that a lens of sufficient covering power is being used.

I also said that by the combined use of swing-back and swing-front the rise-and-fall slide usually inserted in the fronts might be dispensed with. Possibly this latter remark would be the one which your report has given in an incorrect manner.—I am, yours, &c., S. D. McKellen.

18, *Brown-street, Manchester, March* 14, 1884.

CORRECTIONS.

To the Editors.

Gentlemen,—In my last communication to the Journal, which appeared in last issue, a grave error has taken place. I am made to say "Herr Obernetter now employs a new patented process," &c., &c. It should have been *Mr. Sachs* instead of Herr Obernetter. My note was intended to prove that Herr Obernetter's new process of engraving was known and at full work long ago, and patented by Mr. Sachs. The latter gentleman, whose modesty has hitherto prevented him from coming to the front, possesses the highest inventive genius; his discoveries in photography are legion. "Honour to whom honour is due."

In the same communication I omitted to mention the name of M. Thouroude in connection with MM. Perrot de Chaumeux and Londe. These gentlemen have written to me that as the greater part of the honour is due to their colleague, M. Thouroude, they hope I will rectify the error in my next letter to the Journal, and I wish to take the earliest opportunity of doing so.—I am, yours, &c., E. Stebbing, *Prof.*

25, *Rue des Apennins, Paris, March* 17, 1884.

Notes and Queries.

Is there any reason why *l'eau javelle* should not be used in washing gelatine negatives after fixing?—J. Dutton.——In reply: This has been already recommended on more than one occasion.

R. Barnard desires to know the amount of duty chargeable on engravings, photographs, and other pictures sent to the United States of America. ——In reply: On engravings and photographs a duty of 25 per cent. is charged, while the duty on paintings is 30 per cent., unless such paintings are the works of American artists, in which case they are admitted free. On frames for paintings the duty is 35 per cent. Stereoscopic views on *paper* are only 25 per cent., but on those on *glass* the duty is 45 per cent.

C. E. E. wishes to know why two lenses are employed in the formation of a lantern condenser. One lens, he thinks, should answer better than two, as it would stop less light and have only one-half the number of reflecting surfaces.——To this we reply: To correct the aberration of the lens would not be difficult if we had to deal with a radiant placed at a great distance, and the rays from which were to be made converging only in a very small degree after transmission. A short focus, however, would necessitate a deep curve, which implies great thickness in the glass and a certainty of its becoming fractured by the heat; besides which, the spherical aberration of such a lens would be very great and the result altogether bad. By the employment of two lenses both these evils are obviated.

Having a triple achromatic lens, the central component of which is plano-concave with the flat side next to the front, I would like a little information as to the capabilities of this objective. I was informed, when I got it from the friend to whom I am indebted for it, that it was capable of doing a great number of things which were enumerated at the time, but which I have unfortunately forgotten. May I trespass on your kindness to afford me the information desired?—E. B. Smallwood.——In reply: The objective in its complete form will produce a rectilinear picture. It will answer equally well for landscapes, architecture, or groups. For the last-named class of picture no diaphragm should be employed. If the centre and front lenses be removed, the back lens will answer as a single landscape lens. The front and back employed alone in combination will answer for portraits, but will cover only a limited area. We write this on the assumption that the objective is one of the usual triple class.

F. G. H. wishes to be informed whether a lens which is non-symmetrical can be made to produce a photograph that shall be absolutely rectilinear.——To this we reply that mechanical symmetry in the construction of a lens is not at all necessary in the production of a non-distorted photograph. Rectilinear projection is ensured by the rays emerging from the objective in a direction parallel to that at which they enter, and this condition can be ensured by other than symmetrical systems. In reply to the postscript of our correspondent's letter: The best position for the diaphragm in a combination of lenses is not necessarily that at which the distortion is cured or reduced to a minimum. This depends upon the nature of the lens. But the desirable class of lens is that in which, when the diaphragm is best situated for effecting the cure of distortion, it is also best for curing spherical aberration and conferring the most perfect flatness of field.

ALPHA says:—I am desirous of making panoramic stereographs on glass which, when examined in the stereoscope, shall subtend a very wide angle, and permit both eyes to roam, as it were, from side to side of the picture. Kindly say what steps I must adopt in order to achieve this end.——In reply: Without quite comprehending all that our correspondent may mean, we believe he will attain the end desired by taking his stereoscopic negatives with a wide-angle lens of short focus, not exceeding three inches, even if so much. This will ensure a wide angle of view being obtained, to begin with. Next, and of equal importance, comes the method of examination. This can only be effectively done by having achromatic eyepieces of short focus fitted in the stereoscope. By this means the rays from the sides of the picture, oblique though they be, will be transmitted to the eye, and the whole of the picture be clearly seen, the definition of the sides being not inferior to that of the centres of the respective photographs. This ensures the condition required, namely, a wide angle of view, much magnification of the details, and such a width of visual angle when being examined as to suggest a panoramic picture.

ALFRED H. CONWAY desires information with respect to the blackening of brass—not by an application of black varnish, but as an indelible stain. He has tried making the metal quite clean and free from every trace of grease (as recommended elsewhere) and the applying a solution of chloride of platinum, which he purchased under the name of "chemical bronze;" but the stain thus obtained is not similar to what he has frequently seen in the brass work of certain foreign optical instruments.——We believe that he will succeed to his satisfaction by making the brass quite hot—the precise degree of heat he will discover after a few trials—and immersing it in a solution of nitrate of copper; then holding it over a charcoal fire or Bunsen gas burner until it is observed to become black. We have several times seen experts at work, and from this we would say that to produce the best results with certainty much experience is requisite. To blacken brass by this process it is necessary that no soft solder shall have been employed in putting together any portion of the work. When this is the case it is advisable to give the work a grain by immersion in nitric acid, and then to apply either a solution of protochloride of iron or the "chemical bronze" already mentioned as having been employed by our correspondent.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

EXCHANGES.—In our next.

THOS. WIDDOP.—Thanks for kind attention.

A. S.—Thanks; but you do not seem to have grasped the point of the subject you attack.

STEPHEN RAWSON.—The address required is Mr. Archer, optician, Lord-street, Liverpool.

G. T. GRAMMER.—We shall probably treat upon the subject shortly. Justice cannot be done to the subject in this column.

ALF. WILMORE.—Read the report ou the explosion in the present number. From this you may be able to form your own conclusion.

S. E. D.—The collotypes in question are glazed after they are printed. An aqueous solution of bleached shellac is usually employed for the purpose.

FRANCIS FREEMAN.—If you will take the trouble to refer to any of our ALMANACS for the past three or four years you will obtain the desired information.

JAS. HUNTLY.—We are not aware whether the photograph is copyright or not. The only way of learning that is by searching the register at Stationers' Hall.

A. WELSHMAN.—If you will send the instrument to our office we shall, no doubt, be able to inform you for what purpose it is intended. However, we think we may safely say it is for nothing photographic.

W. J. RICHARDSON.—The reason the cotton dissolved in your attempt to make pyroxyline is that the acids were too weak. They must be the full strength given in the formula. The remedy is obvious in the future.

THOS. B.—According to your own showing the transaction was little short of a fraudulent one, and if the matter be contested we doubt much if you will be able to recover. We certainly shall not assist you in any way.

T. J. E. B.—Re-blacken the inside of the lens tube. Doubtless the haziness is caused by reflections from the inside of the mount. You might also, with advantage, paint over the edges of the lenses themselves with black varnish.

NOVICE.—The portrait lens is certainly incomplete if, as you say, there is only one glass in the posterior cell. You had better obtain your money back from those who sold the lens to you. The thing is decidedly imperfect. Never mind who is the maker.

P. P. A.—1. This query is quite unintelligible. Kindly repeat it, and be more definite.—2. Yes.—3. The iodide of starch test, as employed for paper prints, will do quite well for gelatine negatives.—4. Yes; but the plate will be very slow as compared with bromide.

G. A. WINGFIELD.—Unless you are a fairly good hand in using cabinet makers' tools we advise you to send the camera to the maker, direct, for repairs. The accident was very unfortunate, and will necessarily involve some expense, though not very considerable, we imagine.

J. PERCY GRAHAM.—Unless you inform us of the proportion of silver employed in the emulsion, and the quantity put upon each plate, it is impossible to estimate the value of silver per gross. Commercial plates vary considerably as to the amount of silver they contain.

A. W. (Newcastle).—The powder process is certainly the best you can employ. Unfortunately, there is some little difficulty in working such large sizes as you require. In this process much depends upon hygroscopic conditions, which, in our changeable climate, are not easily controlled.

CHROMO.—"Chromotypes" or carbon prints, developed on glass, when mounted with the full gloss, require to be spotted while they are still on the glass—of course before the transfer paper is applied. Instead of using water colours, oil colours must be employed; otherwise, when the picture is wetted, the spotting would be removed.

R. E. G.—Something must be wrong either with the nitrate of silver or the distilled water; otherwise the bath would not behave as it does. Your best plan now will be to neutralise the nitric acid you have added with a solution of carbonate of soda. Then leave it exposed to sunlight in a white glass bottle for a few days. After this filter it, make it slightly acid with nitric acid, try it again, and, probably, all will be satisfactory.

F. AND R. S. JOHNSON.—We do not clearly understand your query. Is it the Talbotype process you require or Talbot's photo.-engraving process? If the former, you will find it described in any of the early manuals on photography; if the latter, you had better procure a copy of Talbot's specification from the Patent Office. Sheet gelatine, such as that employed for glazing prints, is made by coating plates of tin or glass previously rubbed over with ox-gall, with a solution of fine transparent gelatine. When the coating is dry it leaves the plates easily.

RECEIVED.—George Smith; Herbert S. Starnes; W. H. Harrison.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The next monthly technical meeting of this Society will be held on Tuesday next, March 25th, at eight p.m.

THE CALCUTTA EXHIBITION.—The bronze medal and certificate connected with the above exhibition was awarded to Messrs. H. and E. J. Dale, of 26, Ludgate Hill and Little Britain, for their patent multiplex camera back and excellence in photographic camera work.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 26th inst., the subject for discussion will be—*The Preparation of Lantern Slides.* This being a lantern night, members and visitors are invited to bring slides for exhibition.

PHOTOGRAPHY AND ASTRONOMY.—At a meeting of the Liverpool Astronomical Society, on Monday last, the 17th instant, the Rev. T. E. Espin, B.A., F.R.A.S., stated that the work of photographing star-charts was proceeding favourably. In some of the pictures there were stars down to the eleventh magnitude. Several plates were passed round for examination, including one of a fine cluster near Alpha Persei, and another of Prœsepe, showing the planet Mars.—The Secretary announced that the Rev. S. J. Perry, S.J., F.R.S., &c., of Stonyhurst Observatory, had promised to deliver an address, on the 21st April, on *Sun Spots: their Birth and Changes.*

ANOTHER PANIC AT A MAGIC LANTERN ENTERTAINMENT.—On Monday night last, the 17th instant, at Holland's school, Farnworth, near Bolton, Mr. Peter Greenhalgh, exhibitor of dissolving views, gave an entertainment in aid of the fund to provide a new organ for the Wesleyan Chapel, Farnworth. During the singing of a chorus shortly after the commencement of the entertainment there was a loud detonation, followed by a large volume of flame. This caused a rush to the doors by the panic-stricken audience, which was chiefly composed of young people. The explosion arose not from the gas bag, but through the imperfect working of a small tube in connection with the ether vessel. The light used was the "ethoxo-oxygen." Some persons who sat near the lamp were singed about the head and face, and other members of the audience met with a few knocks and bruises, but no very serious damage was done. Fortunately the attendance was not large, or the panic might have been attended with disastrous results.

GLYCERINE IN GELATINE EMULSION.

In the course of the experiments some results of which have been recorded in the past two weeks' issues, we have been led to branch off in various directions with a view of testing the capabilities of glycerine as a medium in which to suspend the silver bromide. It will be remembered that, some three or four years ago, Captain Abney suggested glycerine in place of gelatine for this purpose, the silver bromide after cooking being permitted to subside, and the glycerine together with the decomposition salts being then poured away and replaced by plain gelatine.

This process, for some reason or other, never obtained any great degree of popularity—most probably on account of the feeble suspending power the glycerine possesses as compared with gelatine and other substances; so that, on this ground alone, we should not have again troubled to enter into fresh experiments. But, bearing in mind the extraordinary effect that glycerine has in increasing or hastening the penetration of liquids into animal tissues and substances, it struck us that this power might be utilised to advantage for a double purpose in connection with gelatine films. First of all, in assisting in the rapid and complete removal of the soluble matter from the emulsion; and, secondly, in increasing the permeability of the dried film when submitted to development.

In the latter direction we had previously experimented with other substances—such as starch, dextrine, gum arabic, *et hoc genus omne*—with results that showed there was a possible gain if the attendant disadvantages could be got rid of. We did not expect to meet with, nor are we now prepared to recognise, any gain in point of rapidity from the use of glycerine or any similar substance, as has been claimed by one or two experimentalists, who have apparently mistaken rapidity of development for increased rapidity of impression. This we have never been able to verify; for, though if we develope side by side two plates prepared under identically similar conditions except that one contains glycerine and the other does not, the former will probably be nearly fully developed before the other has fairly started. Still, if time be allowed, the non-glycerine plate will eventually overtake its competitor.

But, as a valuable adjunct to the emulsion during its preparation, we can speak very favourably of glycerine; for, not only does it assist in the rapid removal of the decomposition salts when the jelly is washed, but it further seems to cause a more complete elimination of the semi-colloid matter resulting from the decomposition of the gelatine, which is charged by some with producing "green fog." Certain it is that of two emulsions prepared from the same formula—with the exception of the addition of glycerine to one, and worked side by side through each operation—the one containing glycerine would bear the application of a much stronger solution of ammonia without showing green fog than the other, and this not in an isolated instance, but as an invariable result.

To test the value of the glycerine in assisting rapid diffusion and removal of the soluble salts an emulsion was prepared and divided into three portions, to one of which glycerine was added in the proportion of half-a-drachm to the ounce, to another thirty grains of gum arabic, while the third was made up to the same bulk with water. A pretty large excess of soluble bromide was employed in order to afford a sufficient range of tests. The three emulsions were allowed to set separately, and were then broken up for washing by the same instrument, as close an approach as possible being made to similarity of condition in each case. They were then suspended in muslin bags in separate jars of water, and each tested at intervals to ascertain the progress made in the removal of the soluble matter. The jars were numbered 1, 2, 3, containing respectively in the order named the plain emulsion, the glycerine, and the gum.

Upon testing the washing waters after a lapse of five minutes No. 2 gave a copious precipitate with silver nitrate, the others showing far less—No. 1 rather more than No. 3. In ten minutes No. 2 still showed most result, Nos. 1 and 3, about equal, being decidedly behind. In a-quarter of an hour Nos. 2 and 3 showed equality, No. 1 being now behind. From this point No. 2 gradually showed less and less deposit upon the addition of silver; No. 3 increased until thirty minutes, and then commenced to decline; while No. 1 went on without any apparent increase in its "output" of soluble bromide for about an hour, when it in turn began to decline.

The different waters became free from reaction under the silver test in the following periods:—No. 2, twenty-five minutes; No. 3, forty minutes; No. 1, eighty minutes. This method of washing, be it observed, is not the most rapid, but was the one most conveniently adapted to the purposes of identical treatment.

Now, if we examine these results, they will show that with the addition of glycerine we have a copious and rapid diffusion of the salts from the very first, and easy removal of all soluble matter. The gum arabic, from its more viscous character, resists for a time, but eventually succumbs, and renders aid in getting rid of the soluble matter, which is retained for a far longer period by the gelatine alone.

These results point, therefore, to an application of glycerine which will no doubt prove useful. We may add, incidentally, that with one particular sample of gelatine that "pits" badly the addition of glycerine completely cures the defect.

FLEXIBLE NEGATIVES.

Once more this subject has been brought under the notice of one of the societies—this time that of the London and Provincial Photographic Association.

Several years ago, when collodio-bromide held sway, attempts were made to apply it to paper instead of glass; none of these, however, were attended with such a degree of success as to have led to glass being superseded. Other pellicular systems in addition to paper were introduced, but before these had a chance of becoming developed in the form of being generally worked, collodion emulsion was deposed in favour of gelatine. The union of gelatine emulsion with paper as a support has already proved not only possible but quite practical; and, notwithstanding the great advantages possessed by glass as a basis on which to form the sensitive gelatine film, especially in portrait operations, it does not require much acumen to prophesy that for landscape work one department of gelatino-bromide which will ere long become developed in an extensive manner is that of the employment of paper as a support for the sensitive layer.

What are its disadvantages? That which would at first suggest itself is the fear of the grain of the paper producing an effect, greater or less, of granularity in the print. But it was shown by one of the speakers at the meeting to which reference has been made that even in prints from some Talbotype negatives, to which transparency had been imparted either by waxing or by some other of the means adopted by calotypists for effecting this purpose, the grain seemed to have been practically eliminated, or, at anyrate, rendered innocuous. Since those early times in the history of our art, when the recognised system of imparting transparency to a paper negative was the somewhat primitive method of laying it down upon a heated slab and rubbing wax over it, which melted and effected the desired end, the superfluity being absorbed by blotting-paper—since those days, we say, although the making of paper negatives has been discontinued the art of rendering paper translucent has been steadily advancing, and in this respect we stand upon higher ground at the present time than at the earlier epoch of which we have spoken.

A second disadvantage that might be imagined to be a concomitant of paper as against glass is the inferiority, as regards sharpness, which would result from its employment. This objection, if closely examined, will not be found tenable. The image will not be in the texture of the paper, but superimposed upon its surface in a thin pellicle. This being the case, it stands to reason that, no matter how great would be the granularity resulting from the backing of paper—if any such granularity really existed—the quality of the definition in the paper negative would precisely equal that obtained upon glass. If the printing were effected through the paper support the case would be different; but here the gelatine pellicle and the sensitive albumenised paper are placed in contact during printing.

But sharpness of a high order has been obtained in negatives taken on paper altogether; that is, upon paper which has not received any superficial coating, but contains interspersed throughout its substance the atoms forming the picture. This is the condition that existed in the now-extinct Talbotype process, in which the paper was salted by immersion in a solution of iodide of potassium, and sensitised by a wash of gallo-nitrate of silver. And yet, in Talbot's *Pencil of Nature*, examples of this process are before the world from which it is seen that the sharpness is such as to enable any person, by the aid of a magnifier, to decipher the titles on the backs of books in Talbot's photograph of a library, a further note-worthy element in this photograph being that it is printed on plain and not upon albumenised paper.

It will not, we believe, be said that there exists any exceptional difficulty in coating the paper. A speaker at the meeting alluded to said he laid the paper upon a plate of glass and then applied the emulsion as if coating a glass plate. It is presumable that, after the system comes into more general use, methods will be employed of a description similar to those now adopted in the preparation of carbon tissue. We have coated paper with perfect success by means analogous to those employed in albumenising, namely, by floating.

With respect to the nature of the paper that will prove best as a support: stiffness conjoined with homogeneity and transparency are requisites which claim the chief place in the selection. *Papier mineral* has been mentioned as suitable, and, despite its thinness, it may perhaps answer well. Still we think it will in practice be found to be too thin.

At this period we are introduced to something which may turn out to be just what fulfils every requirement. In *Recent Patents*, in this week's Journal, we publish the specification of an invention which, if it prove all that its introducers claim on its behalf, may serve a useful end as a support for gelatine emulsion. Suitable paper as regards thickness is rendered transparent by impregnation with copal varnish. When dry the surface is smoothed by means of powdered pumice-stone, and a coating of isinglass is then given, followed by treatment with ox-gall. It is probable that the transparency and stiffness imparted by the varnish will give to the paper such properties as will obviate the necessity of carrying out the patented invention in all its details. We have no doubt that varnished paper has, for purposes of negative photography, been tried by many.

The applications of negative pellicles of the character here spoken of are too numerous and obvious to require noticing in this article. We trust soon to learn that this application has been brought to such a degree of perfection as to be very generally adopted.

THE *SEL D'OR* TONING PROCESS.

From the published reports of the discussions on the causes of the fading of silver prints, which have recently taken place at several photographic societies, it appears that considerable misapprehension exists as to the older methods of toning. Evidently several gentlemen who have taken part in these discussions are labouring under the impression that the *sel d'or* process and the process of toning and fixing in one operation are identical. This is an entire misconception, for the processes are totally distinct and dissimilar; in fact, there is as great a difference in the manipulation of the two as there is between the present alkaline process and the old plan of toning and fixing in one solution.

This being the case, we shall here explain the *sel d'or* process, so that it may be seen how widely different, both in principle and in practice, it is from the process of fixing and toning in one operation. The latter process will be found described in an article in our issue for February 22nd. We deem it necessary that attention should be called to this matter now; otherwise, as time wears on, the two processes may be confounded and, eventually, considered as one and the same. Also, results which have been produced by the one process may ultimately be credited to the other and thus become misleading, if such be not already the case.

Sel d'or (salt of gold), it may be explained, is a double hyposulphite of gold and soda. It contains one atom of the former salt to three of the latter, together with four atoms of water of crystallisation. It is formed by adding one part of chloride of gold in solution to three parts of hyposulphite of soda, also in solution. The resulting *sel d'or* is then precipitated with alcohol. The salt thus formed crystallises in fine, needle-like crystals. It was once an article of commerce, and used to be put up in small bottles in the same way as chloride of gold, but it was somewhat dearer. In a price list, bearing the date 1854, now before us of an establishment which at that time had a reputation for cheapness, *sel d'or* is quoted at four shillings per fifteen-grain bottle, while chloride of gold is only three shillings for a similar quantity. Now, we believe, it is not made commercially at all, as we do not find it in any price list of photographic chemicals; even in the very complete list of Messrs. Hopkin and Williams it is not mentioned. As *sel d'or* is practically obsolete, in our further remarks we shall speak in the past tense.

The salt was first introduced by M. Fizeau for toning—or "gilding," as it was termed—daguerreotypes, and was employed in the following manner:—After the picture had been fixed with hyposulphite of soda and thoroughly washed a dilute solution of the *sel d'or* was poured on, and a gentle heat applied to the plate. In a couple of minutes or so the picture was generally sufficiently toned. Gold toning of the daguerreotype image, besides much improving its appearance, undoubtedly conduced to greater permanence.

If our memory serve us rightly, it was the late Mr. Thomas Sutton, B.A., who first introduced the *sel d'or* process for toning paper photographs. At the time of its introduction, the advantages claimed for this process was that it yielded greater permanence than was secured by toning and fixing in one operation, and this was borne out by experiments made at the time. Little or no over-printing was required. Further: the toning solution could be prepared at the time of using, and only so much as was required for immediate use need be made. A freshly-made solution secured the pictures being toned with gold. This could not be relied upon after the compound toning and fixing bath had been kept for some time, and was only used occasionally. The *sel d'or* process of toning was chiefly confined to plain paper prints, as it was not found to work so satisfactorily with albumenised paper. Even with the slightly-albumenised paper then in vogue it was recommended to treat the prints with diluted ammonia in order to render them more easily permeable by the toning solution. As time wore on and the albumen on the paper was increased *sel d'or* toning was only employed for plain paper.

The plan usually pursued with this method of toning was as follows:—As the *sel d'or* of commerce, notwithstanding the high price charged for it, often contained far less than the theoretical proportion of gold, it was customary, therefore, to prepare it extemporaneously as required. Here is the formula:—Six grains of hyposulphite of soda were first dissolved in four ounces of water, then two grains of chloride of gold were dissolved in a similar quantity of water, and the two solutions mixed by pouring the gold solution into that of the hyposulphite of soda, which had to be vigorously stirred at the time. It was imperative that the gold be added to the soda, and not the soda to the gold. Finally: six or eight minims of hydrochloric acid were added, and the solution was then ready for use. If the chloride of gold contained much free acid the hydrochloric was omitted.

After the prints were taken from the pressure-frames they had to be thoroughly washed to eliminate all the free nitrate of silver. This was essential, otherwise the prints were liable to become yellow and the toning bath was also injured; therefore the prints after washing were usually immersed in a dilute solution of common salt prior to toning. In the *sel d'or* process the printing was not carried nearly to the same depth as was required when the compound fixing and toning bath was employed. The toning generally occupied but a few minutes with plain salted or ammonio-nitrate paper, but with albumenised paper, even with the small proportion of albumen then used, the toning action was much slower, as we have already explained. When the prints were toned to the desired depth they were rinsed in water and then transferred to the fixing bath. This was simply a plain solution of hyposulphite of soda of a similar strength to that now employed for fixing prints toned by the alkaline method, the time allowed for fixing being about the same as at present.

From the foregoing description it will be seen that the *sel d'or* process is, in every way, distinct from that of toning and fixing in one operation. In the former process the toning and fixing are separate operations, the same as with the alkaline method, and the toning is completed before the prints are immersed in the fixing bath; while in the latter process the prints are practically fixed before the toning action is commenced.

Since the alkaline process was introduced no other system of toning has really been employed; hence *sel d'or*, like the compound toning and fixing bath, has become a thing of the past. We should, therefore, probably not have alluded to the subject at all, but we notice that many of our younger brethren in the art-science are confusing the two processes, and are evidently labouring under the impression that pictures toned and fixed in one operation have been toned by the *sel d'or* process.

PROFESSIONAL *VERSUS* AMATEUR PHOTOGRAPHERS.

The ever-increasing number of amateurs who within the last few years have joined the ranks of photography is a positively startling fact. In estimating the results that have followed, and are likely to follow, the introduction of gelatino-bromide plates, it is one which many professionals look upon with undisguised alarm—whether rightly or wrongly, we propose to discuss. Such is the unreasonableness, such the want of proper feeling, displayed by some that they choose to term "interlopers" the very men to whom modern photography may be fairly said to owe its existence. We cannot avoid thinking that it shows to what a height of selfishness, or, perhaps, we ought to say, egotism, some persons can soar.

Photography is almost essentially the product of amateur experiment, the main result of which has been given to the world untrammelled and unpaid for. We all know of the early patent which was taken out for a photographic method, but it was soon relinquished entirely for the public benefit. Commercial photography—photography, that is, of magnitude—may truly be said to date from the introduction of the collodion process. What was done for its inventor by those who had risen to affluence through his means—the man who, practically, had invented a new art, a new industrial pursuit, a means of livelihood by which we are fairly within the mark in saying tens of thousands gain their daily bread—the man who enabled scores of decayed gentlemen, discharged clerks, and unfortunate tradesmen, not to speak of worthless handicraftsmen, the broken-down butchers, bakers, and candlestick makers who rushed at the new means of making a lazy living, soon to be a luxurious one, without training being needed or knowledge required? What was done for him? We should be ashamed to name the contemptible sum that was raised for the benefit of those he left behind him.

Are not, rather, the professional photographers themselves interlopers? Gelatino-bromide is to all intents and purposes entirely the outcome of amateur efforts; yet, if we were to see at the dealer's counter some of its earlier exponents side by side with a member or two of those great firms who order a few thousand plates at a time, we are afraid that the former asking for a few dozen of the things he had called into existence would have to bide his time till the interloping professional had been supplied.

It will not suffice to say that amateurs of this kind are not meant—that the amateur who buys a small apparatus and a good supply of chemicals, and goes about taking his friends' portraits in every direction, is the class which is objected to—for to imply this would be making things still worse, and would be tantamount to saying that "we will not murmur at those people photographing without pay or reward who are likely to invent something new that may turn to our benefit; but we don't want anyone to come photographing if we are not to gain by it." We appeal to the broader-minded—whom we really believe form a far larger proportion of our readers—if we have not rightly stated the way in which many professional photographers speak. Thus we see it is as ungenerous as it is illogical to complain of the influx of amateurs, and we do not think it will be difficult to show that it is equally unwise in every way to offer the "cold shoulder" to them.

The absurd action of a firm of American photographers, who notified the closing of their account with the stock-dealers with whom they did business on account of these dealers selling materials to amateurs, has been well laughed at by the intelligent men of business on either side of the water; but it is a fair example of the feeling we describe and deprecate. On many grounds we should advise professional photographers to encourage and assist the increase of amateurs. An example will illustrate our meaning. Let there be two or three well-known photographers in a town, one of the three only sharing our views. If he show courtesy to amateurs he will enlarge the circle of his *clientèle*, and, more than that, it will be a strange neighbourhood if he be not able to obtain an occasional pupil. This, even to a prosperous photographer, is all pure gain, as he could make appointments for lessons. If he charge (we could give instances where this is done) a guinea for a lesson of one hour it will be fairly-paying work, and he will naturally both increase his reputation and his business—the other two photographers we have supposed, as a matter of course, losing to that extent.

Many professional photographers have made acceptable additions to their income by teaching and supplying apparatus; though we have heard them complain that there is so great a demand for apparatus that the dealers and makers do not care to allow them a discount or commission, they being able to sell at first hand all they can produce. This is a point upon which it is not our province to enter; but we may be sure that the inexorable law of supply and demand will very soon cause a levelling of inequalities of this character.

We have kept to the last the most formidable difficulty—formidable in appearance only—the expectation that the more work done by amateurs the less there will be for professionals. This we, and and many with us, believe to be a pure figment. Photography, nowadays, is a very different thing from what it was even a dozen years ago. The pictures which then would have delighted their originals would not be looked at now, on account of the increased excellence that characterises photographs from the average professional and the added work of the retoucher. Now we would ask—Is it reasonable to imagine that any everyday amateur could be, in the brief time which he can give to the work, at all likely to produce anything that will compete against good average professional photography? On the face of it the supposition is absurd. Hence, no loss could occur from any such course; and, further, the difficulties that the amateur will find to beset the production of really good work would, through the very publicity obtained, place the professional photographer in a better position and enhance the reputation of his skill.

Finally: we might add that, if in intimate circles *cartes* and cabinets of friends were produced, a knowledge of human nature would enable us to predict that the selfsame people would come to be taken by the professional portraitist; and thus, as in all other ways, would amateurs aid the professional photographer and improve his status.

AMONG the Americans who are at present on a visit to this country, one of the most distinguished—certainly *the* most distinguished in the transatlantic world of mechanical science—is Mr. Coleman Sellers, of Philadelphia. For several years prior to 1864 Mr. Sellers was the American correspondent of this Journal, and the trenchant and able manner in which he treated of the various current matters of interest in those days will be remembered by many. Rarely has any journal been blessed with so genial a correspondent as Mr. Sellers. The cares of an increasing business (now one of the largest and most important in the world) compelled the retirement of Mr. Sellers both from his position as our correspondent and also from that of an executive officer of the Philadelphia Photographic Society, greatly to our regret and to the loss of photography. Previous, however, to his retirement he rendered a service of unspeakable importance to our art-science in completing arrangements by which Mr. M. Carey Lea became his successor. Of Mr. Lea's valued services this is not the place to speak. With regard to Mr. Sellers it is enough to say that in the optics, the mechanics, the chemistry, and the practice of photography he was quite at home. We trust that he will enjoy his visit to Europe.

WE regret to learn, from the Chicago *Eye*, of the stoppage of the Chicago Dry Plate Manufacturing Co., caused, as stated in the official circular to the creditors, "by the trade having fallen off to such an extent that the expensive plant, indispensable in producing their products, left the Company without capital enough to tide itself over the period of dull trade." We hope that the creditors will arrive at such conclusions as will enable the Company to resume operations.

JUDGING from an announcement in an American contemporary the writing diamond appears to be an instrument unknown to its readers, but after which they are assumed to have aspirations, in order to place the numbers or names indelibly upon their negatives. The writing diamond has been more or less in use in this country since photography on glass was first introduced; but its employment is not now much resorted to, owing to the adoption of systems of numbering and naming the negatives which meet with more general acceptation.

THE word "art" in its various forms—fine art, artistic, &c.—always acts like a red flag upon a bull in some quarters photographic; hence we feel a little diffident in re-introducing it at a time when it may possibly again start the old discussion, though, after all, such discussion carried on in a proper spirit is calculated both to interest and instruct. Definitions innumerable as to the meaning of the word have been given, but those to be found in even first-class dictionaries do not embrace in a satisfactory manner that shade of meaning which has formed matter for argument so often in the pages of our own and other journals. The editor of the great lexicon—the *English Dictionary*—now in course of publication, the first number of which was reviewed by us a few weeks ago, writes to the *Athenæum* on the word "art," asking for references on the use of the word "as it is used in *art* journals, by *art* critics, by Mr. Ruskin in writing on *art* and artists, or by anyone who speaks of early Italian *art* or modern English *art*." He asks—"Is it not a curious illustration of the traditional character of English lexicography that this, which is probably now the first sense of *art* that comes up to one's mind, is not, so far as I know, to be found in any dictionary, English or American?" . . . "Even dictionaries which have added *art union* to their vocabulary, and define it as 'a union of persons interested in art,' leave posterity to conjecture whether this *art* in which the nineteenth century was interested was 'skill,' 'tact,' 'cunning,' 'speculation,' 'the principles of science practically carried out,' 'a device, a project,' or 'whatever has been made by man' (*e.g.*, the Griffin—tall hats)"! What food for argument will there not be when Part II. of the dictionary is issued!

THE wish expressed by *La Nature* that Mr. Cecil V. Shadbolt might make new conquests in the aërial world is in a fair way of being realised, for that gentleman is already contemplating making further ascents in the near future, the "Sunbeam" having been undergoing repairs nearly all the winter, and being now almost ready to be launched into space again. The balloon had become very sticky, so that Mr. Dale, as Mr. Shadbolt informs us, had a long and difficult task with it. Our readers will be interested to know that the indefatigable balloonist is having another and a smaller balloon made, which will be capable of accommodating three persons. It will have a bright and gay aspect when soaring aloft, the fabric being put together in alternate red and yellow gores, and it is expected to be ready early in summer, when it is Mr. Shadbolt's determination to do still further and better photographic work.

ONE of the earliest suggestions as to the use of the spectroscope was that it would serve as a means of qualitative chemical analysis, and, gradually, experimenters came to consider that it could be used even as a quantitative mode. At a meeting of the Royal Society, on the 13th instant, Professor Hartley, whose photographed spectra are so beautifully executed, read a paper summarising the methods that had been employed for the purpose, and then gave an account of the length and strength of metallic lines in solutions of different strength. Magnesium gave the strongest effect, and arsenic the weakest, so small a quantity as one part of the former in 10,000,000,000 parts of water being detected. The immense value of photography in researches of this character can scarcely be estimated, and as it eliminates all personal equations it forms a permanent register of the highest value.

FOR many purposes it is very desirable to possess a substance which, applied to vessels or tubes, should be as impermeable as possible to heat, and an interesting addition to our knowledge on the subject has been made by Mr. J. J. Coleman, in a communication to the Philosophical Society of Glasgow. In a room heated to 100° Fahr. he placed a number of boxes containing ice and of about a foot cubical capacity, first placing them in a tin box, allowing four inches of space all round, and then packing with the various materials. He tried also a second series in a room of 60° Fahr. temperature, and obtained the following results, the numbers indicating the amount of ice melted in a given time:—

Room at a Temperature of 100° Fahr.

1 Silicate cotton	100
2 Cotton wool	122
3 Sheep's wool	136
4 Infusorial earth	136
5 Wood charcoal	160
6 Sawdust	163

Temperature of Room 60° Fahr.

1 Silicate cotton	100
2 Hair felt	117
3 Wood charcoal	120
4 Wood shavings	125
5 Gasworks' breeze (coke dust)	230
6 Air spaces of 1 in. alternated with wood 1 in.	280

A box well packed with silicate cotton, after the manner of a Norwegian cooking stove, would form a very easy mode of cooking emulsion without the aid of extra heat and its attendant necessity of care and watchfulness.

THE same gentleman exhibited a most ingenious thermometrical arrangement of his invention, which he termed a "discontinuous thermometer." It consisted of a series of tube bottles arranged in a row in a wooden frame, the liquid contents of which became frozen successively as the temperature lowered, commencing with an olefine (paraffine), solidifying at 100° Fahr., the series consisting of olefines until 32° is reached, when the series is continued to 40° below zero with mixtures of glycerine and water.

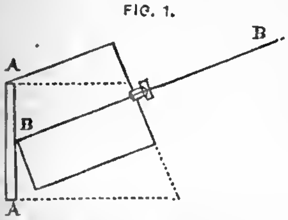
WE lately called the attention of our readers to the state of affairs at the Paris Observatory, and the objections offered to the sale of the grounds to raise funds for making the necessary alterations suggested. At its last private sitting the Academy of Sciences debated the question of the sale of the observatory grounds in order to find the funds for erecting—not a substitute, but a branch observatory, as it were. No conclusion was arrived at, and the discussion was adjourned for fifteen days. The majority of the Academy is of opinion that it would be desirable to grant the credits required for the erection of a new establishment; but many members are against the sale of any parcel of ground. They contend that the present position of the observatory must not be deteriorated under any pretence whatever. MM. Wolf and Janssen delivered addresses defending the *status quo.*

DISTORTION BY THE CAMERA.

In writing some little time since on *Distortion by Lenses*,* distortion by the camera was left for future treatment; and, as the subject in the form of a discussion on swing-backs and rising-fronts is now on the *tapis*, it seems a fitting occasion for considering the principles involved.

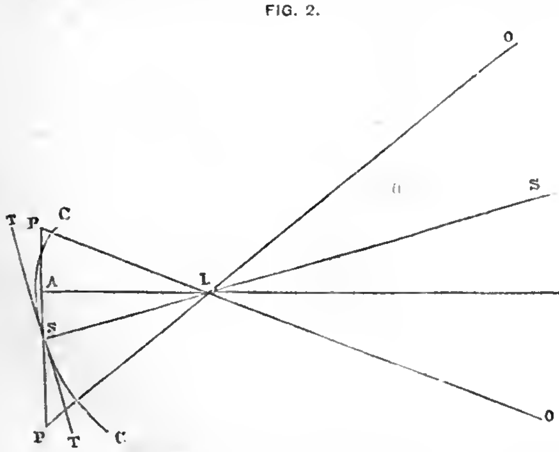
As to the relative merits of the swing-front and the swing-back: it is merely a question of mechanical convenience, and there is no advantage optically in the one arrangement over the other. With the swing-front, however, it is imperative that there should be also the rising-front; otherwise with the back kept vertical to avoid distortion there would be even less of a high building included on the plate than there would be with the whole camera square and rigid. To prove the identity of action of the swing-front and swing-back, let A A (*fig.* 1) be the camera back, and B B a line from some point in the building which has to be represented in the centre of the field of view. Now, whether the camera be tilted and the back swung vertically, or the camera be fixed with its back vertical and the swinging and rising front used, the lens must occupy the position in which it is shown on the line drawn from the centre of the object to the centre of the image, and it can make no difference optically whether the leather and woodwork of the camera take the ordinary form indicated by the continuous lines or that of the camera with the swing-front shown by the dotted lines.

FIG. 1.



With respect to the use of a swing-back or of a rising front: when a difficult architectural subject—such as a tall building taken from a short distance—has to be photographed, the advantages on the side of the rising front are so great that it is almost always, if not in every case, to be preferred, provided that the lens employed has a sufficiently large angle of view. I am glad to be supported in this view by the practical experience of Mr. F. York, who stated at one of the societies some little time since that he used a rigid camera and a high rising front in preference to the swing back. In illustration of the difference between the methods: let P P, *fig.* 2, be a plate, and P O, P O be lines from the top and bottom of the subject to be delineated drawn through the lens L. Now, assuming the lens to have a flat field, its plane of definition will, in the case of a rigid camera and rising front, be P P, at right angles with the axis A A of the lens and identical with the surface of the plate. In the case, however, of a tilted camera, with the back swung vertically to preserve the perpendicularity of the lines, the plane of the definition will be T T, at right angles to the axis S S of the lens, and only cutting the plane of the plate along one line. It is obvious that the greater part of the picture will be considerably out of focus. This is additionally aggravated by the fact that the top of the building is further from the lens than the centre, and to be in focus would require the back to be swung in the contrary direction from that which it has had to take, in order to preserve the uprightness of the lines. The foreground is also nearer the lens, and, for a similar reason, ought (so as to be in focus) to have the back also swung in the contrary direction from that in which it has been tilted.

FIG. 2.



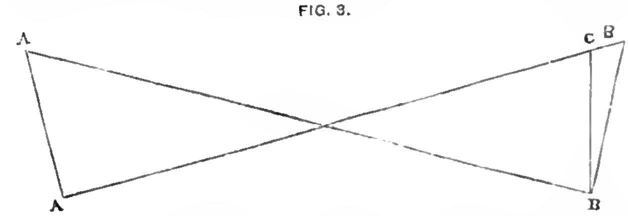
The case of a lens having a curved field, as seen in the line C C, shows an advantage with respect to the upper half of the plate, the curve of definition cutting the plane of the plate in two places and being for some distance very near it; but a corresponding disadvantage on the lower half, where the two lines P P and C C are seen to recede more violently from each other. Opticians have always recognised the desirability of having a flat field of definition, and in lenses of the wide-angle doublet kind a considerable approximation to this result has been attained.

An additional reason for preferring the rising front to the swing-back arises from the fact that the top of a building is generally much more lighted than the base, and the foreground commonly requires most light of all. Now, with a camera tilted, the circular opening of the diaphragm is presented to somewhere near the centre of the building, and the top and the foreground receive equally the smaller amount of light that comes from the opening of the diaphragm, as it is seen somewhat sidewise in an elliptical form. When, however, the camera is kept square and the front raised the lower part of the picture has the full circular opening of the stop presented to it, letting in the greatest amount of light, whilst the top (the most strongly illuminated) part of the building and the sky have the narrow, semi-edgewise view of the diaphragm presented, and the supply of light cut off accordingly, thus equalising to a considerable extent the illumination of the whole picture.

Of course the use of a rising-front instead of a swing-back involves the employment of a lens having a larger field of view than the size of the plate which it is intended to cover. There are many lenses, however, that will cover a considerably wider angle than that occupied by the plate with which they are generally used, although I notice a tendency of late years to cut down the size of lenses with a view to greater portability. I think that this is to be regretted. I know it is urged that leaving a little more margin on the lens, so as to increase its width of angle, involves that the edge of the field included in this extra angle will not be so well-defined as the remaining portion. To this it may be answered that it is often useful to have width of angle of light even if the definition in that extra width be not perfect. How often does it happen, when using a lens to its full field of light, that the sky shows as a circle with the edges of the plate as black corners! If a little more glass had been allowed at the edge of the lens this would be prevented, and the sky without much definition in it would certainly be to be preferred.

In connection with the subject of distortion by the camera, that of correcting such distortion by special methods of copying the distorted photograph may properly be considered. The method which will accomplish this in any particular case will depend upon how the distortion has been produced, and the manner of correcting it may be divided into three cases, illustrated as follows:—Let A A (*fig.* 3)

FIG. 3.



be a map which has been copied with the camera not square to it. The camera back B B' has been swung to obtain an even focus, and the copy of the map, although right in length and average width—that is, width across the centre—will show one end narrower than the other. If the picture is now to be corrected by recopying, and is tilted to a sufficient extent, the camera remaining square as at C B', the lines may be restored to squareness; but the proportions of the original will be altered, and the photograph will be too short in proportion to its width. If the picture be put square to the camera, and the back be swung to restore parallelism of the side

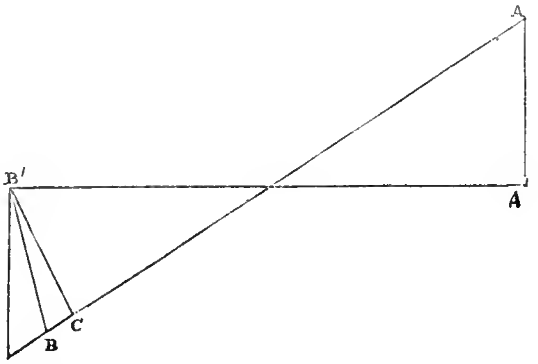
* The British Journal of Photography, 1883, p. 722.

lines, the photograph will make the length too great in proportion to its width. The true way in this case is to swing both the copy to be corrected as A A, and the camera back B B′.

In the second case, suppose B B′ to be the side of a slanting wall, or the side of a hill, and that the camera back A A has been swung to get top and bottom in focus. This case differs from that of the map, in that it is not proposed to represent the flat surface as it would appear if looked down upon from such a height that a line at right angles to the surface of the wall or side of hill would be the line of sight, as that would make the wall or hill appear vertical instead of showing its slope; but the line of sight is to be parallel with the earth's surface. In this case the photograph to be copied must be slanted as at A A, and the camera back kept square as at C B′.

In the third case, let A A, *fig.* 4, represent a building which has been photographed with a tilted camera, and with the plate B B as

FIG. 4.



with a rigid camera it would be at right angles to its axis. To set this right in copying, the picture must be presented square to the camera, the back of which should be tilted. The picture was already too short in proportion to its average breadth, and if it be presented otherwise than vertically square to the camera it will become more so. If, in addition to pointing the camera upwards, the bottom of the camera has been swung inwards as at B′ C, the case resembles that of the map first mentioned; but, as in consequence of the difference of the conjugate foci, the inclination of the camera back to its axis will not be so great as that of the front of the building is to the same axis, the slope of the picture to be copied must not be so great as that of the back of the camera with which the corrected copy is to be made. W. E. Debenham.

STANNOTYPE.
No. VIII.

As a matter of convenience, when several reliefs have to be developed at once, the grooved zinc trough will be found far preferable to any other form of vessel, being at once compact and roomy and, at the same time, holding the films in such a position that the dissolved gelatine readily washes away from the surface of the relief. Clearly there is a gain both in time and trouble when the development of several films is carried on at the same time; for, even when personal attention is devoted to the operation during the whole period, there need be no waiting or waste, as must be the case where only a single relief is in question.

Circumstances may, however, arise in which it is desirable or necessary to operate upon a single film, in which case the grooved developing trough is needless; indeed, when the operations are likely to be generally on a small scale, a preferable plan is to employ a circular oval basin, or an ordinary pie dish of suitable size, in which the plate carrying the relief is placed face downwards and left to develope itself. Here the gelatine, as soon as it is dissolved, sinks by its own weight, leaving a fresh portion of the surface to be acted upon. Regularity and rapidity of development are thus secured.

Where the operations are on a small scale it will probably not be considered worth while to adopt the refinement of an automatic system of regulating the temperature during development, though for various reasons this plan is to be preferred. The amateur will probably be content to trust to some simple means of retaining the temperature at a point somewhere between the limits allowable by means of a small gas jet or spirit flame, or by renewing the water as it cools. The latter plan is likely to cause irregularity in development, as when the water is allowed to sink below a certain temperature it ceases to exercise any solvent action upon the gelatine, but merely causes it to swell and become slimy, in which condition it is dissolved rapidly and irregularly upon the sudden change to water of a higher temperature. The danger in the other case is that, unless the arrangements are carefully adjusted, there is the chance of the temperature rising too high—a matter which must be most carefully guarded against, especially during the earlier stage of the process. In fact, the conditions to be observed here are identical with those which prevail in ordinary carbon printing, only a greater amount of care is necessary.

Thus, though we have given 120° as the limit of temperature to be used, we may increase this by ten or fifteen degrees towards the end of the operation, especially if the tissue appear to have been over-exposed; but, if such increased temperature be applied at the commencement, the probability would be that the film would become loosened from the glass, and blisters and reticulation make their appearance. Those who are familiar with carbon printing will appreciate to the full the increased difficulties in this and similar directions that the thicker relief tissue involves, and will readily recognise the necessity for and value of extra care in little matters.

Should a slight detachment of the film occur from any reason, the difficulty may sometimes be overcome by laying a strip of waxed glass along the detached edge, and clamping it thereto by means of a couple of American clips. The arrangement is not an elegant one, nor does the presence of the clips add to the convenience of the developing operation; but where the treatment offers the chance of saving a relief it is worth adoption. A very convenient clip for this and other purposes may be made by slipping half-an-inch of india-rubber tubing over two narrow strips of glass, so as to bind them together in the middle. If a piece of thin glass rod be passed transversely through the rubber tube and between the slips of glass it forms a "knuckle" upon which the slips of glass hinge, the rubber tube acting as a spring, and the strength of the clip being regulated by the position of the transverse rod.

If a slip or slips of glass be attached to the relief in this manner they must be allowed to remain until the development is complete and the plate thoroughly dried. They may then be removed by carefully inserting the point of a penknife underneath the slip, when, if properly waxed, it will detach itself readily.

Experience alone will enable the operator to judge when the development has been carried sufficiently far; but, as a rule, when the image presents much of the appearance of an ordinary negative as regards density, and the surface appears even and free from smears of partially-dissolved gelatine, the action may be considered as complete. It is a good plan, when the development appears to be finished, to place the plate in a dish of clean and tolerably warm water for a few minutes; and if, on removal, no smears of gelatine are evident when the plate is tilted, a final rinse in clean, cold water completes the operation.

It is not absolutely necessary, but some operators prefer at this stage to treat the relief with alum in order to further harden it, but it is a question whether such treatment is not superfluous. However, no harm can accrue from a five minutes' soaking in a strong and carefully-filtered solution of common alum, after which the plate is again rinsed and placed to drain for a few minutes upon blotting-paper. The final treatment consists in immersing the plate for twenty minutes or half-an-hour in a dish of strong methylated alcohol, which, like all the other solutions employed, must be well filtered and perfectly free from dust. This precaution is specially necessary with the alcohol, as much of the commercial article contains a considerable quantity of sediment which, if it become attached to the surface at this stage, will cause endless trouble in the way of spots.

After immersion in the alcohol the plate is drained and removed to a warm, dry place, carefully protected from dust, until it is thoroughly desiccated. When apparently dry it is a good plan to heat the plate to about 150° Fahr. for a few minutes, in order to ensure the complete removal of all moisture and to harden the film. So long as the relief contains any trace of moisture it is not only in a soft condition and liable to be easily damaged, but it is not in its best state as regards sharpness.

A few words may be said on the subject of the apparent sharpness of the image during development. The beginner will be frequently mislead by the seeming want of sharpness of the moist relief, and will imagine that this is the result of imperfect contact between the transparency and the tissue; but such is not the case. The swollen state of the gelatine image is the cause; and, when completely developed, if the plate be held at an angle with a sheet of white paper, the image will be seen to present a considerable delicacy of detail, though, if viewed by direct transmitted light, it may seem "woolly." During the early stages of development the presence of considerable proportions of swollen, soluble gelatine causes the want of sharpness to be very noticeable; but this gradually disappears, and to the practised eye the apparent sharpness of the image is a good test of the progress of the operation. When dried the relief contracts and becomes perfectly sharp in its minutest details, provided always the original is sharp and contact has been secured between the printing surfaces. The difficulty in securing contact is not so great as might at first sight seem likely, if the tissue have been properly dried after sensitising. If it be allowed to curl up, and especially if it be over-dried, perfect contact is impossible, as the necessary pressure will fracture the tissue rather than flatten it. If, however, proper precautions are observed to secure its drying flat, a very slight degree of pressure suffices.

As regards the symptoms of over- and under-exposure, these are the same as in ordinary carbon printing. In the former case difficulty in retaining the tissue in contact with the glass during development, and refusal of the gelatine to dissolve except at a very high temperature, are plain signs. An over-exposed relief is not necessarily useless, as by the employment of very hot water and prolonged action a sufficient depth may be secured. Under-exposure, on the other hand, is fatal to success, as the thin layer of insolated gelatine which forms the image fails to give a sufficient degree of relief. Slight under-exposure may be remedied by modifying the colour-strength of the ink; but if the relief be a very shallow one there does not exist a sufficient gradation from light to shade to give a satisfactory result with any kind of ink.

If the tissue be of the right thickness and contain a moderate amount of colour, and the exposure and development have been correct, the finished relief, when viewed by transmitted light, should present the appearance of an ordinary negative of moderate density. But it does not follow that because this appearance is wanting that the relief is useless. An over-exposed relief may make a perfect printing surface while presenting a considerably veiled appearance by transmitted light. The depth and gradation of relief are the only true tests.

SAFE LIGHT.

No. I.

A general revulsion of feeling has lately taken place against the red light—most usually considered the only safe one to employ in the dark room for developing gelatine dry plates; and experience has shown that the most rapid plates now in use can be safely developed in a degree of light which a short time back was considered by most people to be absolutely inadmissible. There can be no question of the fact that by degrees it is becoming much more general for rapid plates to be easily and successfully developed in a light which a year or two ago would have been, in the opinion of careful workers, considered highly dangerous.

The explanation of this change of opinion is not difficult to find. It is not that the yellow or yellowish-green light now advocated is safe, or even approximately safe, but that the plates are more reliable.

In the earlier days of gelatine plates, every effort was made to produce the highest possible degree of sensitiveness by special treatment of the emulsion. Manufacturers were working in the dark as regards their knowledge of the treatment most effectual; but not in darkness as regards the light necessary for the coating, drying, and packing before the plates could be offered for sale. One of the great difficulties has been that of securing a sufficiently safe light with which to work without affecting the quality of the plates.

Now, it is most clearly established that the sensitive silver salts which are employed for photographic purposes can be exposed to direct light for a certain time without injury to their photographic value—indeed, in some cases, with positive advantage. In the old collodion days it was a common practice to deliberately expose the newly-sensitised plate to light before exposing it in the camera, with the result of practically producing a plate which was very appreciably more sensitive than a similar one prepared in the same way, but which had not received this preliminary exposure to light.

A curious instance of this came to my knowledge. A photographer, in the course of his practice, having heard of this preliminary exposure as increasing the sensitiveness of the collodion, gave it a very careful trial but failed altogether; but finding that the slightest preliminary exposure inevitably produced fog, he challenged one of the advocates of the method to prove its worth or fallacy. The gentleman who went to his studio to conduct the trials found the facts as the photographer had stated. The slightest preliminary exposure of the collodion film to light produced no extra sensitiveness in the plate, but certainly caused fog in developing. He was not, however, long in finding out the cause, which was the simple one that the usual yellow calico blind in the photographer's dark room had gradually become bleached, and so admitted a considerable amount of white light into the dark room. That this was the case was proved at once. A new blind was procured, when instantly the collodion plates became far less sensitive than they had been previously; but a preliminary exposure to light at once restored them to their maximum sensitiveness. It was, therefore, evident that the photographer had, without knowing it, been working under conditions of light which increased the apparent sensitiveness of his plates.

I have no doubt that gelatine dry plates have the same peculiarity; indeed, Mr. W. K. Burton has shown that such is the case. In his experiments he tested a plate out of a batch by the sensitometer, and found it to register a certain number. He then took a quantity of similar plates, and exposed them to the diffused light of a room lighted by a candle for various times, finding that with each increase of preliminary exposure a higher number was registered on the sensitometer, until at last a point was reached when the ordinary developer produced fog.

I have found the same thing with the ordinary sensitised albumenised paper. Some years ago I had to employ a Vogel's sensitometer, in which the scale of tints consists of a series of strips of paper each a little shorter than the preceding one, and numbered consecutively in opaque figures. No. 1 was only one thickness of paper, No. 2 two thicknesses, and so on to 24, I think. The exposure was read off in a similar manner to Warnerke's sensitometer—the highest visible number. The strip of sensitised paper was, of course, long enough to cover the whole scale, but it most generally happened that I only wanted to expose to (say) No. 7 or 8. I, therefore, for a second exposure utilised the other end, on which no impression was visible. The second exposure was, however, less reliable; for not only did it seem to come quicker—though that I never really tested—but at the other end, where before only 7 or 8 was visible, one or two numbers more would come out. This, to my mind, makes it doubtful if sensitised paper is quite reliable as a photometer test, unless it be carefully protected from light until the time of exposing.

Now, I take it that this is exactly what usually occurred with most dry-plate manufacturers in the early days. Every one was comparatively inexperienced, and operations (which after a time could be well done in a dim light) required then considerably more; so that, unknowingly, the plates had received all, or very nearly all, the preliminary exposure which they could bear without fogging on the application of an ordinarily-powerful developer. Such plates as these evidently could not be manipulated by the consumer except in the very safest possible light. Add to this the fact that the consumer was also inexperienced, development was very slow compared with the rapid process he had been accustomed to with collodion plates, and the difficulty of judging density also demanded more prolonged exposure to his developing-lamp. With all his care the plates would fog. How often did it occur to him that the plates *might* have been in just the exact state for fogging, even if developed as received from the maker? I had some which I felt certain were in that state. I believed that my light was as perfectly safe as any artificial light could be made; so I made the experiment of developing two plates of the same batch, one by my red light and the other in absolute darkness, with precisely the same result—fog all over, and a distinct mark in each case where the packing papers were inserted between the plates.

Unquestionably large numbers of plates were sent out on the verge of fogging from the treatment they had received during manufacture. Whether from an unsafe light in undue quantity being administered to them during the process, or whether from inexperience in the process of making the emulsion, it matters little if the fact be allowed. If they would just bear the test of exposure and development in the manufacturer's studio under the most favourable conditions, he could confidently assure the tyro that the systematic fogging of which he complained must be due to his light not being safe. What he did not say (perhaps because he did not know) was that any plate ought to be able to support a certain amount of exposure to light and yet not show any sign of fogging with the strongest developer; that any plate which will not bear that test is useless, as, no matter how safe the light may be which is used for developing, &c., the plate must of necessity receive some diffused light reflected from the sides of the camera during exposure.

The poor struggler, however, naturally concluded that it must be the developing light that was in fault. He put another thickness of red fabric over his lamp, and, possibly, getting hold of some plates which were a little nearer the mark, secured some negatives free from fog. He was then convinced that it was his light which had been wrong all the time, and thus the era of the deepest possible ruby light came about.

It must not, however, be forgotten that in the North of England it has been the practice to use canary medium, and not the ruby light so general in our latitudes. The fact was publicly stated at one of the London meetings a couple of years since, but only elicited the criticism that the northerners must have been working slower plates. Possibly they might have been slower in the sense that they had not received the preliminary exposure necessary to bring them to fogging point, but they would bear the canary light, which is anything but safe. GEORGE SMITH.

ON THINGS IN GENERAL.

"No tree in all the grove but has its charms,
Though each its hue peculiar; paler some,
And of a warmish grey; the willow such,
And poplar that with silver lines his leaf;
And ash, far stretching with umbrageous arms.
Of deeper green the elm; and deeper still,
Lord of the woods, the long surviving oak."

WHAT slight verbal alteration would be needed to adapt these lines of Cowper to the present controversy on dark-room windows! The canary medium is pretty well understood; but the "cathedral green," which is not cathedral green at all, is enough to drive the average photographer far on the road to Colney Hatch! I am afraid many of the disputants are not in the habit of going either to a cathedral or even their own parish church, or they would soon find the hues of the window panes differed as much as the verdure so well depicted in the lines with which I have headed my communication. The four hundred and sixty-seven squares in the window to my right in my favourite seat at church are of a pale yellowish-green, while the three hundred and eighty diamonds, familiar to my gaze in past years, were of a deep sea-green (with three deep blue-greens, evidently the result of "repairs"); and all possible shades between are doubtless to be seen in one church or another. By-the-bye, what a relief it is to count these squares all ways when the sermon is long and not clever! This, however, is a digression; we will leave the further elucidation of the original matter in the very able hands of the gentleman who first set the ball rolling. I may just say I would rather he had to explain than I had how one thickness of green glass "takes the heating effect of the red and orange rays out of the light, and preserves or restores its yellow colour." With this little puzzle I leave the subject.

I observe that my reference to Mr. S. Fry's remarks has not been left without reply by that gentleman. I think he had better have been content with the points which, indubitably, he had made, and not have attempted to hold on to everything he had uttered. The man who never makes a mistake is a—— well! I will not fill in the hiatus! Mr. Fry said the beauty of sulphite lay in its keeping the fingers clean, and when I say it does not act so with mine he upholds his statement by asking me to use an old knife (instead of sulphite I presume); and then informs me how to get rid of the stains that he said would not be present. Further: about this removing the stain by rubbing with weak acid—a nice long rubbing it sometimes is, too—it has to be followed by plenty of washing; or, when the hands are afterwards washed with soap, *presto!* the stain, or most of it, is back again.

Another correspondent, "Coleswegen," writes—"Free Lance criticised Mr. Hume Nisbet's paper in the Journal of January 18, 1884, but did not explain how far his picture was to be from the eye to cover the whole of the landscape or part. I suppose that the focal distance of the lens which he used for his picture and the axis of both picture and landscape are what he means when he talks of exact superposition." I meant what I said; nothing so silly as "Coleswegen" suggests ever entered my mind. How the focus of a lens and the axis of a picture and of a landscape, whatever they may be, are to be exactly superposed must be explained by "Coleswegen." The feat is beyond the power of anyone else. What I said was that a correctly-taken photograph, if rendered transparent enough for objects to be seen through it, would, if held *at a proper distance* between the eye and the view it represented, exactly coincide, line for line and point for point, with the lines and points of the scene depicted. As I have just stated, I meant what I said, and was not called upon to say what the distance would be. I was not writing a mathematical treatise, and it would have been absurd to introduce such a detail.

Anthony's Bulletin, too, is complaining of me for doubting its correctness in giving the famous Mr. Kurtz the credit for having been the first to introduce retouching. So far as its actual introduction is concerned, I should think it must have been simultaneously introduced by a score of people. I know that I ameliorated the rugosities of the complexion in negatives close upon a quarter of a century ago. The question is—Who first made it the rule of his business to retouch negatives? Let the *Bulletin* say when Mr. Kurtz did this, and I think I can show him the work of a man who retouched all his negatives before Mr. Kurtz entered the ranks of photography. If I am wrong I will own it candidly; if not, I am sure my opponent on this point is equally fair and will be equally candid.

I hasten to assure Mr. H. S. Starnes that I had not for a moment any idea of accusing him of plagiarism when I wrote of having seen something like his remarks in Mr. W. Harding Warner's papers. I referred to their tone and scope, the audacity of their conceptions, and the originality of their ideas. I am quite sure Mr. Starnes is literally right in saying he has never seen any articles of anyone which were like the theories he had set forth. I can safely say that I also have not. Mr. Starnes excites interest by speaking of having come across some experiments by Bunsen and Roscoe in which they unite chlorine and hydrogen by light. These experiments must be very interesting, and, I daresay, further research might lead to other similar accounts. I should not be surprised to learn that both these gentlemen had, for instance, published some remarks about the spectrum; the subjects are very closely connected.

Among the patent specifications lately published I notice one for storing chemicals, by Mr. G. D. Macdougald. Seeing that for preserving his chemicals he employs a sealed tube, like a chloride of gold tube, that requires to be broken before being used; that he breaks them by means of a file-cut or other indentation, as has been done for a century by chemists; or that he soaks paper in the chemical and then dries it to get a definite quantity, just as is done in medicine and surgery, I should think the patent requires the pruning-knife before being of much use.

I often read Mr. W. H. Harrison's remarks with a deal of pleasure; but I must confess to a complete feeling of mystification as to the meaning of a portion of his article on a pyro. sulphurous developer. When he obtained sulphurous acid through decomposing sulphite with sulphuric acid, where did it go to in developing? Are we to understand that it did not combine with the ammonia, or that a grain of sulphite of ammonia goes as far as a multitude of grains of sulphite of soda?

I always look out for novelties in the reports of societies' meetings; but I rubbed my eyes when I saw announced as a novelty at the Glasgow Photographic Association the discovery that one cause of fading was hypo. in the mounts—a fact which was not, the speaker believed, generally known! I should have thought that of all causes this had more prominence given to it than any other. The speaker seemed to have taken much trouble in the matter, which was praiseworthy, though a very slight knowledge of current literature would have enabled him to devote his energies to better purpose. By-the-bye, how did he find traces of *hypo.*, sulphates, and *chlorine* in the same mounts?

The Chairman of the Newcastle-on-Tyne Photographic Association made a most interesting observation with regard to gold toning. He took a sheet of paper, divided it, exposed the two halves under a vignette mask, toned one and left the other untoned, all other operations being the same. Contrary to the usually-received opinions the toned half faded soonest after being exposed to the sun. The fading of prints is a very intricate subject, and our thanks are due to anyone who throws fresh light upon it, as Mr. J. B. Payne thus does.

Dr. J. K. Tulloch, at the meeting of the Dundee Photographic Society, gave an excellent, simple illustration of the effects of reflection in producing halation, and I commend his few remarks (see THE BRITISH JOURNAL OF PHOTOGRAPHY, page 167), to the attention of those interested in the subject.

I notice that at the Manchester Photographic Society the question of swing-backs led to a rather mixed series of statements. Mr. S. D. McKellen thinks it desirable to correct the statement put in his mouth, but the Chairman does not qualify the words reported as being his—"that placing the plate at too great an angle to the lens must have a distorting effect." When the camera is tilted this very placing at an angle is to prevent distortion. FREE LANCE.

OLD PHOTOGRAPHS.*

ANTIQUITY OF FIFTEEN YEARS' DURATION.

IT may be asked—What is an old photograph? In my own mind I have fixed the date at any time anterior to fifteen years.

I feel quite satisfied that it is carelessness or want of the necessary chemical knowledge on the part of the photographer which has induced the idea that silver prints are not to be trusted in matters of permanence. It must also not be lost sight of that after Disderi introduced the popular form of photograph (the *carte-de-visite)* hundreds took up photography as a means of increasing their incomes, looking upon it as an El Dorado—a mine of wealth—the majority of those adopting it just getting a superficial knowledge of how to make a negative and produce a print. This knowledge proved sufficient to flood the country with photographs that are by the irony of fate a lasting insult to all right-minded photographers, and deservedly obtaining the

* Concluded from page 180.

sneers of artists and an evil reputation that has, unfortunately, yet to be lived down. Combinations of occupations that, to say the least of it, sounded peculiar, namely, 'chimney sweep and photographic artist," "shoemaker and photographer," "hair cut and portraits taken," were frequently met with, but are fortunately becoming more rare year by year.

Happily, however, photography in the present day is shaking off these attachments, and has become of sufficient importance to be pursued alone as a means of living and a source of wealth. It has been found an art capable of doing something more than merely pander to personal vanity and amusement; for it would be difficult at the present time to overrate its importance in industrial, scientific, or artistic occupations. The claims made for it to be a fine art of itself can hardly be admitted, but works having every claim to the title are by its means not unfrequently produced, and in the future bid fair to be much more numerous. This Society, seeing the advantages to be gained by the improvement of the artistic side of photography, instituted the monthly competitions, and it is to be regretted that more enthusiasm has not been evinced in the promotion of a work so productive of beneficial results. The subjects now selected for the next competition are both numerous and varied, and the members of this Society will do well if they take the matter up in earnest and make it thoroughly successful.

I am afraid I am somewhat travelling away from the subject of my paper, which should properly be confined to "old photographs;" but I could not resist the opportunity of alluding to our competitions, for I think they are calculated to improve that phase of photography in which there is the greatest need of improvement. One conclusion we cannot fail to draw from the examination of good, old photographs, and that is—they were in every way equal in manipulative qualities to very many of the modern ones; and also that old photographs have proved that silver printing, *when it is properly done*, is a permanent process, and not one of those evanescent, fugitive, unreliable methods of picture-making with which it is so unfairly credited. The older specimens of silver printing have been from negatives developed with acid pyro., or from negatives produced by the "converting process," as it used to be called; that is, a positive was taken, treated with a solution of iodine and mercury, which had the effect of increasing the density and destroying the positive appearance by reflected light it originally possessed. The results were generally harsh and deficient in half-tone, the shadows being represented by clear glass and consequently printed with the well-known "soot-and-whitewash" effect.

INFLUENCE OF ADAM-SALOMON.

It was some time before the general run of photographers discovered that increase in exposure was nearly all that was required to make a sufficiently-dense image at one operation. The elaborate performance of making a negative bath that often as not ended in fog and stains deterred many from "going in" for direct negatives. Saving residues had not become generally known, and a bath that would not work satisfactorily was incontinently shot down the sink. This, with the high price of silver nitrate, acted as a considerable check to experimentalists, and the more certain, if worse, way of proceeding was for a long time the adopted process. You will understand I am not alluding to the few specially-dexterous workers, but to the majority of those who took up photography, and who, living in the country, did not possess the opportunity of comparing results. I think that the first *really* turning over of a new leaf was after M. Adam-Salomon and one or two other foreign exhibitors showed some specimens of their work at an exhibition of the Parent Society, at the rooms in Conduit-street, Regent-street. In the present day the amount of enthusiasm those exhibits created can hardly be realised. The name of M. Adam-Salomon was in every photographer's mouth, and they were not long attempting to rival the sculptor-photographer, and with the utmost beneficial effect on photographic work. Mr. V. Blanchard came to the front with excellently-managed, large portraits of the Salomon tone and character, and his exhibits were for a long time anxiously sought. Others, too, were not far behind, and the old fashion of portraiture gradually died out.

In landscape, the work also of Mr. F. Bedford stood out from the rest as a lighthouse on a rocky coast, and was the envy or admiration of many less successful men. There were, however, other "good men and true" a credit to the time. I merely mention the names I have as having particularly struck me as workers to be imitated, and without drawing any invidious comparisons. It may be borne in mind even from the first that, irrespective of manipulative excellence, art qualifications did much to raise photographers to the pre-eminent position they hold; for even then as now artistic treatment, if less understood, commanded notice and respect. The works of the late Mr. O. G. Rejlander were almost entirely dependent on artistic qualities for their popularity. The only regret is they were not combined with cleaner manipulation. Had he lived in these days of rapid dry plates, the world might have been astonished at the results he could undoubtedly have achieved.

ADVANTAGES OF INDIA PAPER.

I have endeavoured to collect a few specimens of early work to show you to-night, and in criticising them you must forget for the time the beautiful and artistic work of the present day, and only think of them as good examples of the general work of that time. Where possible the history of the production is written on the back; but with many of the specimens their age is their only history. In calling your attention to the transparencies by Ferrier, which I have had in my possession for more than twenty-five years, I think they compare favourably in every respect with work of the present day. The price then, at Messrs. Horne and Thornthwaite's, was 12s. 6d. each. They have retained their brilliancy and colour unchanged, although they have been kept in both damp and dry rooms, with no other care than being placed in a grooved box. I may also mention that some of the prints shown have been for some years stored in a portfolio in a very damp room—so much so that they were quite mouldy—and with this result: the mounts have suffered, but the prints themselves have not. Could we say as much for water-colour drawings? In one case the print had been laid down on India paper on plate paper. The plate paper had become covered with mildew spots, but not one appears on the India paper, nor is the photograph at all affected. I may remark that on looking through a number of mounted photographs I did not find one instance of fading where the prints had been laid down on India paper, but when attached to ordinary white mounts some had commenced to yellow at the edges. A great number of my prints I used to mount at home, using gum arabic, and they have stood the test of damp without showing any sign of deterioration. Others have been mounted by professional mounters, and I am unable to say what substance they used; at anyrate it has not affected the prints. I will not now trespass on your patience by adding to the length of my paper, which has already exceeded the usual limits of the opening of a discussion; but trust some of the points to which I have adverted may elicit from you, experienced photographers, some practical and useful remarks. Mr. H. P. Robinson has kindly sent some examples of old work, upon which I have written a few remarks. EDWARD DUNMORE.

LECTURES AT THE ROYAL INSTITUTION.

PHOTOGRAPHIC ACTION.

CAPTAIN ABNEY continued his experiments in demonstrating the action of acids on the photographic image. A sheet of paper containing bromide was exposed to light, and then written upon with solutions of different acids, such as hydrochloric, nitric, and sulphuric acids. When these acids had acted the image refused to develope. The action was attributed to the acids appropriating an atom of silver from the sub-bromide, and not to the oxidation.

The lecturer mentioned as a curious fact that the image which had been destroyed by oxidation, due to peroxide of hydrogen and other oxidising agents, could be revived by passing a current of natural hydrogen over the surface, the hydrogen taking away the oxygen first of all, and then, if continued, reducing the saline salt to the metallic state. Two more experiments showed the destruction of the action of radiation through the agency of iodide and bromide of potassium. In both cases the plates were exposed to light and then washed and dipped in a solution of bromide or iodide of potassium. Whilst still moist they were exposed to the image of a negative. The plate treated with iodide was developed as a wet plate on the screen, whilst the other was developed by ferrous oxalate. The reversal of the image in both cases was very marked, and required but a short exposure. The lecturer stated that Fox Talbot's patents included the production of positive images on paper by this means, but the *rationale* of the result he himself had investigated some few years ago. In these cases it was necessary that free oxygen should be present or the reaction could not take place, the products of decomposition depending for their formation on its presence.

After some further remarks on the oxidation of the image the subject of phosphorescence was introduced for the purpose of exemplifying the destruction of the action of one kind of radiation by badly-timed oscillation of another kind. A series of tubes containing various sulphides was illuminated by the electric light, and then phosphorescence was studied by the violet phosphorescent substance which forms the essential part of Balmain's paint. A lozenge-shaped beam of light was allowed to fall on a phosphorescent plate, and it became strongly illuminated where the beam fell. It was then illuminated entirely, and a lozenge of light passing through red glass was allowed to fall on the illuminated plate. Instead of a bright image it was now dark. A selection of coloured glasses were next placed in contact with the light phosphorescent plate and again illuminated with the electric light. Some increased the brightness, whilst others diminished it. These glasses were next passed through the spectrum, and it was shown that those glasses which allowed only rays of low refrangibility to pass through caused a diminution of the brightness. The spectrum was next allowed to play on an exposed phosphorescent plate, when it was seen that the green, red, ultra-red, and ultra-violet rays diminished the luminosity, the blue rays increasing it. A diagram was thrown on the screen giving the phosphorescent spectrum, by which it was demonstrated that the action below the blue part of the spectrum which illuminated the plate was inactive in destroying the phosphorescence. This, the lecturer stated, was an exemplification of badly-timed vibrations stopping the vibrations of the atoms in the sulphide of calcium.

A piece of ice placed against a luminous phosphorescent table immediately darkened the part in contact with it, whilst a heated flat iron strongly increased it. The explanation of this was given, but we should have been glad if the lecturer had entered into it a little more fully. The clock, however, evidently had something to do with the brevity of his explanation, and we hope that it may be gone into further next Saturday. Several of the experiments in phosphorescence were new at the Royal Institution, and were evidently appreciated. The lecture was brought to a conclusion by a demonstration of the beauty of Rowlands' concave gratings, with one of which some splendid spectra were thrown on a transparent screen. Captain Abney demonstrated that all the apparatus necessary for utilising them for spectrum work was a source of light, a slit, the grating, and a photographic plate on which to examine the image. The grating was the largest we have yet seen, the used surface measuring something like six inches by four and a-half.

The lecturer was well supplied with light, for he had the dynamo machine, an oxyhydrogen lantern, and the electric light all at his command.

On the next occasion we may presume that the real business with the spectrum will be commenced. It should have been treated of in the third lecture according to the syllabus, and if a syllabus be of any use at all it ought to have been moderately adhered to.

HISTORY OF PHOTOGRAPHY IN GLASGOW.

[Written in 1861, and re-read before the Glasgow Photographic Association on March 6th, 1884.]

I AM put down in the circular to read a paper on *The History of Photography in Glasgow*; but, before doing so, I will sketch out, very faintly indeed, the commencement of the photographic art, which has become pre-eminently a scientific art, as it requires no peculiar genius in its cultivators; whereas the painter and sculptor excel only according to the high gifts they possess for their divine art.

It was in the sixteenth century that, in searching for the "elixir of life," the alchemists found out the great fact that salts of silver became blackened by exposure to light; and in the eighteenth century this wonderful phenomenon engaged the attention of Petit; in 1722, Scheele, the Swedish chemist; in 1777, Ritter, and other celebrated men. Yet but very little progress was made in the science until Wedgewood, in 1802, assisted by Sir H. Davy, produced pictures; but these took too long an exposure and were, besides, unfixed—the fixing agents being then unknown. Hyposulphite of soda was only discovered in 1819, by Sir John Herschel, and iodine in 1812. Without these discoveries being known photography would never have reached its present point of perfection. Wedgewood may, therefore, be claimed as the earliest photographer.

Then Joseph Nicèphore Nièpce, in 1813, partially succeeded in fixing these silver pictures; but his efforts were directed to reproduce, on a metal plate, an image in the camera in order to change it into an engraved plate, and when he and Daguerre went into partnership, in 1827, it was abandoned. In 1833 he died. His son Isodore went in with Daguerre, and it was not taken up again till after Daguerre's discovery in 1839. Professor Arago, in announcing it to the scientific world, said—"France has adopted this discovery, and is proud to present it as a gift to the world." Daguerre received a pension of 6,000 francs and Nièpce 4,000 francs for their invention.

M. Berres and Dr. Donné were the first to change the daguerreotype into an engraved plate.

M. Bayard, a very successful photographer, used to paint names and devices on unripe peaches while growing, which, on being ripe and the paint washed off, left the image on the peach.

Sir John Herschel was next known in the field; then Talbot, who had been working at it from 1834 to 31st January, 1839, when he published his Talbotype process. Hunt and others followed, and the scientific world was astonished at the discoveries made known from time to time.

Till America produced the single combination lenses it took from half-an-hour and upwards for portraits, whereas by the American plan a few seconds sufficed. Mr. Beard, in London, used it. Now, however, with the double achromatic lenses, much greater perfection has been attained.

I will now, so far as certain data and my memory serve me, trace out the *History of Photography in Glasgow*, and I hope that I may be corrected by any member present wherein I may be wrong.

One of our members, Mr. Samuel R. Brown, being in Paris in 1839, received from M. Daguerre one of his pictures, which on his arrival in Glasgow he exhibited in Royal Exchange-square, and which I recollect seeing. Dr. Paterson (to whom the photographers in Glasgow are largely indebted), as usual with him in anything new and worthy, set to work at it at once. Mr. Brown himself and another member, Mr. Hugh Wilson, were also engaged in it, but who has the precedence I cannot determine; perhaps they will be able to do so.

In June, 1842, I got over one of the American apparatus—I think the very first in Glasgow, and which I have still. The lenses are about four inches diameter. It has a very short focus and works only a one-sixth plate, and can be worked in a room at a common window. It was so powerful that I worked with it by the north light, and I exhibited two portraits in the exhibition of paintings as having been done by a northern exposure.

In 1841 the first professional photographer who came to Glasgow was Mr. Edwards, who opened in Buchanan-street (opposite the Arcade), and who in dull weather used to secure the loan of my camera. The glass of his place was entirely blue, as was then the custom. In the same year Mr. Treffray also began at the corner of Union-street and Argyle-street. Now came Mr. Pickering, and in 1846 Mr. Bernard commenced; then the art made a rapid advance—in fact his pictures were splendid. Messrs. Borthwick and Stanley next came, and in 1849 Mr. Hughes succeeded Mr. Bernard. Then Mr. Gardner, Mr. Young (1850), and Mr. White successively came forward, the daguerreotype process alone being worked by all the above.

In June, 1851, Archer's collodion process was published in the *Art Union Journal*, and within five months afterwards Dr. Paterson not only made the collodion, but produced excellent pictures by that process. He communicated the new mode to his friend Mr. King, Mr. Duncan Brown, myself, and many others, and he may fairly be said to be the father of the collodion process here, as he most willingly communicated any knowledge he acquired to all inquirers.

Professor Taylor has also been the means (through his interesting lectures) of producing many excellent photographers, both amateur and professional. I have met with many of them and they speak highly of the Professor's ability and knowledge of the art.

Our President, Mr. Kibble, must now rank and be awarded the first place amongst our amateurs (which are legion since the collodion process), not only for his great attempts but for their quality, and his indefatigable exertions in perfecting an instantaneous process in which he has been so successful, and specimens of which I am sure all of you have seen.

I hope I will be excused when I make no attempt at enumerating the names and abilities of such a multitude of amateurs and others as are working the art in all its various styles, as it would be both invidious and injudicious at this meeting.

Within two years (from the simplicity and cheapness of this new process) we had establishments for it alone opened by Messrs. Dessurne, (March, 1852) Urie, Taylor, and McNab (May, 1852), when the daguerreotypists had to follow in the wake; and now the collodion process has become general, I do not know if a daguerreotype could or would be taken in Glasgow. I think we cannot omit mentioning one name which for coloured positives stands almost unrivalled—I mean that of Mr. Douglas, one of your Council.

The month of June, 1856, ushered in a new feature in the art here when Mr. McNab exhibited his coloured specimens at the foot of Buchanan-street and elsewhere. I have seen crowds looking on admiringly at these pictures, and I am glad that Mr. McNab has not only reaped golden opinions but golden rewards for his bold attempt.

Mr. Werge, Mr. Urie, and Mr. Stuart (who commenced in 1855), Mr. Peebles (an excellent calotypist), Mr. W. Young, Mr. Bowman, and Mr. Cramb have all followed in this new channel, and Glasgow can now feel proud of her high position in the photographic world.

I have, therefore, given you the brief outline, which to have been filled up with all the details that might have been given would have occupied too much of your valuable time; and I would take it as a kindness if any errors that may have crept in may be corrected by those who can do so.

ANDREW MACTEAR.

PHOTOGRAPHY IN COURT
